Characterisation and numerical simulation of the Lower Manawatu Catchment hydrogeological system. A thesis presented in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Earth Sciences at Massey University, Manawatu, New Zealand

Supervisor:
Dr Alan Palmer, School of Agriculture and Environment, Massey University.

Co-Supervisor:
Dr John Begg, GNS Science.

Doctoral Oral Exam Convenor:
Professor Huia Jahnke, School of Maori Knowledge, Massey University

Internal Examiner:
Associate Professor David Horne, School of Agriculture and Environment, Massey University

New Zealand Examiner:
Dr Clint Rissmann, Adjunct Senior Fellow, Waterways Centre, University of Canterbury/Lincoln University

Overseas Examiner:
Professor John Tellam, University of Birmingham, United Kingdom

To my mother Samia

In memory of my father Ibrahim

With love and eternal appreciation.

Abstract

The Lower Manawatu Catchment (LMC) hydrogeological system presents an example of extensive stratified heterogeneous aquifers. A conceptual model was developed for the system through systematic characterisation of its geology, soil, climate, hydrology, hydrogeology and hydrochemistry. Numerical groundwater flow modelling provided an effective integrated framework for the analysis. The developed knowledge and models are useful for the identification and comparison of land and water resources management options in the catchment.

The research involved the development of a soil moisture balance modelling code to evaluate recharge. Stratigraphical modelling has been possible through incorporating imaginary lithological well logs and stratigraphical cross-sections in data-sparse areas. Geological material heterogeneity was represented in the groundwater flow model through hybridising zonal and pilot point calibration techniques. The developed soil moisture, geology and heterogeneity modelling techniques have universal applications.

The study indicates that the LMC hydrogeological system is more suitably represented as a continuous groundwater flow system rather than a sequence of discrete aquifers and aquitards. Average groundwater recharge is estimated at about 25% of average rainfall. Average baseflow is estimated at about 10% of the average runoff, the equivalent to more than half the estimated average recharge.

The LMC groundwater resource is mainly tapped at shallow depths, the locus where most of the interaction with surface water occurs. Catchment-scale steady-state numerical groundwater flow modelling suggests that in average groundwater abstraction may have been depleting overall surface water flow by about 5%.

Groundwater levels in the LMC were found to be generally stable, implying sustainable resource development. Rising groundwater levels noted in the eastern and southern outskirts of Palmerston North may be related to prolonged practice of

irrigation. No evidence of land use impacts on groundwater quality was found in the catchment. Nitrate concentrations are believed to have been kept at acceptable levels in groundwater due to denitrification stimulated by extensive organic content in some geological units.

This thesis represents a one stop shop for information on groundwater in the LMC. The knowledge and tools developed through this research have immediate use in the LMC and elsewhere, and they provide solid basis for further work.

Acknowledgements

This thesis would not have been completed without the relentless support of my supervisor, Dr Alan Palmer. I am greatly indebted to him and grateful for his guidance. I am also thankful to Dr John Begg of GNS Science for co-supervising my research and for his invaluable insights and reviews. Alan's and John's encouragement meant a lot to me and I cannot thank them enough.

Gratitude is due to Dr Jon Roygard for encouraging me to start this journey and providing essential resources at the initial stages of the research. I also thank Clare Houlbrooke for introducing me to the Manawatu geology and hydrogeology.

This research would have been greatly lacking without the virtual climate data provided by Dr Andrew Tait of NIWA. Other important data have been provided by good colleagues in Horizons Regional Council. I particularly acknowledge help from Maree Patterson, Abby Matthews, Stacey Binsted, Stephen Collins, Sean Hodges, Ron Estall, Brent Watson, Raelene Mercer and Jeff Watson.

Peter Hurn collected most of the groundwater level data used in this thesis. I acknowledge his dedication and punctuality in gathering that information. Acknowledgements are similarly due to the drillers in the region who have been unremittingly collecting and reporting lithological information from the wells they drilled, particularly Lyle Sharratt of Wanganui Well Drillers Ltd, Neil Richardson of Richardson Drilling Co, Richard Webb of Richard Webb Limited, and Philip Webb of Nevill Webb & Son Ltd. That data have been critical to the research.

The support of my wife Amal, our daughters Karma and Dalia and sons Ibrahem and Mohamed has been inestimable, and I would like to thank them wholeheartedly for that.

I dedicate this thesis to Professor Zekai Şen of Istanbul Medipol University and Professor John Lloyd of the University of Birmingham for whom I owe my passion for hydrogeology.

Chapter 1 Introduction

1.1 Background

One of our most valuable resources is the water in the ground beneath our feet (McCarron & Zarour, 2005). Toebes (1972) estimated that 80%, or 1.7×10^{12} m^3, of New Zealand's fresh water lies under the ground. Stewart and Bidwell (2008) contemplate that in 2007 groundwater accounted on the national-scale for nearly 10% of the water used by industry, 25% of the water used for domestic supply, and 80% of the water used by agriculture. Groundwater springs and baseflow are also important in sustaining flows in rivers, maintain wetland ecosystems and support many subterranean life forms, particularly during dry periods. Nevertheless, groundwater is often the least-understood component of the hydrological cycle and is commonly undervalued (White & Rosen, 2001). In part, this may be due to its nature as a dynamic, invisible resource that makes it difficult to conceptualise. Another possible reason could be that historically surface water was easier to exploit in New Zealand, so there has been limited interest in gathering hydrogeological data and undertaking groundwater studies.

With increasing demand and environmental restrictions on surface water, groundwater is becoming the preferred and perhaps even the only available water supply option in some areas in New Zealand (Zarour, 2008). Groundwater is also becoming more valued by the community due to the increased awareness of its interconnectedness with surface water and that quantity and quality of surface water and groundwater are inseparable.

In the Manawatu-Wanganui region, within which the Lower Manawatu Catchment (LMC) is located, groundwater provides more than 40% of the overall consumptive water demand (Horizons, 2007). Licenced groundwater abstraction in the region has nearly doubled over the period 1997-2007 (Zarour, 2008). In the LMC groundwater is used for human and animal drinking purposes, irrigation, some

industries and supports wetlands and other surface water forms. Zarour (2008) estimated that $53x10^6$ m^3 of groundwater were extracted for various purposes from c. 5,400 wells through the LMC in the hydrological year 2007/2008.

Despite its obvious importance to the environment, the community and the economy, groundwater in the LMC remains poorly understood and largely an underrated resource. The hydrogeology of parts of the LMC had been studied but many areas have never been investigated and the catchment's groundwater system has not been considered holistically. Moreover, previous studies commonly derived conflicting conclusions regarding the extent, nature and dynamics of the hydrogeological system and there has been a lack of suitable methods to satisfactorily represent the area's hydrolithostratigraphy and realistically simulate its complex hydrogeology. A sound and comprehensive understanding of the resource is fundamental to managing it beneficially and sustainably and new techniques are needed to enable sound hydrogeological analysis of the stratified heterogeneous aquifer system in the LMC.

1.2 Research objectives

This thesis is principally aimed at establishing a robust understanding of the groundwater system in the LMC through systematic conceptualisation and numerical modelling. Achieving this objective required the development of a new geological modelling technique that employs imaginary wells and cross-sections and a new aquifer parametrisation procedure that amalgamates zonal and pilot point model calibration methods to appropriately represent geological stratification and hydraulic heterogeneity in the studied aquifer system. The conceptual model presented provides a realistic framework for effective environmental planning and decision-making and the developed numerical models can be used as tools for assessing the feasibility of various environmental management options. The developed new geological and hydrogeological modelling approaches can be utilised in geological and hydrogeological work globally.

1.3 Hypothesis and challenges

Most previous investigators were inclined to define the LMC groundwater system as a sequence of alternating glacial-time, gravel dominated alluvial aquifers and interglacial-time, sand dominated marine aquitards and aquicludes, in which upward hydraulic gradients can occur only due to aquifer confinement by aquitard or aquiclude strata. This research hypothesises and proves that the LMC hydrogeological system is more appropriately conceptualised and modelled as an integral groundwater flow system that comprises a sequence of glacial and interglacial times sediments that are hydraulically continued throughout the entire three-dimensional (3D) extent of the hydrogeological system, which is hydraulically connected to surface water in the catchment. Within this conceptual framework, downward hydraulic gradients characterise recharge area settings and upward hydraulic gradients depict discharge area settings (Freeze & Cherry, 1979; Tóth, 2009).

Legitimate models simplify reality without forgoing important components or traits of the simulated systems. They must be based on correct and sufficient data, realistic assumptions and implement sound and defensible methods. The conceptualisation of the LMC groundwater flow system presented in this thesis is based on interdisciplinary synthesis of various types of data including information and knowledge on soil, geology, climate, hydrology, hydrogeology, hydrochemistry and land use. Numerical modelling in this study is intended to provide an ultimate integrated framework for hydrogeological analysis.

From the onset of the research, it was clear that the modelling of the LMC groundwater system would be a challenging undertaking due to data limitations and the lack of readily usable methods for realistic simulation of the system. Special analyses had to be undertaken to generate some necessary datasets and new techniques had to be developed to be able to realistically model the LMC stratified, heterogeneous aquifer system. Modelling the LMC groundwater system involved the following challenges and workarounds:

1. Poor definition of recharge areas, mechanisms and rates:

   Geology, geomorphology, soil, land use, land cover, climate and surface water data have been analysed to define recharge areas and a soil moisture balance (SMB) model was developed based on the United Nations Food and Agriculture (FAO) Penman-Monteith equation (Allen *et al.*, 1998). It was necessary to correlate soil types from the New Zealand Fundamental Soil Layer (FSL) (Hewitt, 2010) to the United States Department of Agriculture (USDA) Soil Texture Classification (STC) soil types to enable this analysis.

   The developed SMB model can be easily accustomed to other locations in New Zealand and internationally, providing a simple useful tool to assess groundwater recharge, crop water demand and surface runoff. It could be further enhanced to calculate contaminant loads (e.g. nutrients) resulting from various historical and planned land use scenarios.

2. Ambiguity of lithological well-log data (drillers' descriptions of drilling cuttings):

   An approach had to be devised to transform drillers' lithological descriptions of borehole drilling cuttings into lithostratigraphical units usable in 3D geological modelling. This approach is particularly relevant to young (Pliocene to Present) glacio-eustasy sequences. It can be used in similar geological settings in New Zealand and other countries to help with general geological research and natural resources investigations.

3. Inadequate spatial coverage of lithological well-log data:

   A new geological modelling methodology had to be developed using imaginary wells and cross-sections to compensate for the unrepresentativeness of certain areas and depths in the available lithological well logs dataset. The developed method assimilates conventional manual geological cross-section drawing practices with modern, computerised geostatistics-based geological modelling techniques. It has global

applications and can facilitate the construction of geological models for various purposes. There is potential to integrate more data types into the process, including surface and subsurface geophysical data, structural geology measurements and remote sensing.

4. Aquifer stratification and heterogeneity:

   Existing aquifer parametrisation techniques can be used to simulate stratified heterogeneous aquifers like the LMC sequence. However, the resultant simulations would not be realistic as they either assume homogeneity within individual model layers or unrealistically oversimplify the lithology of the modelled aquifer by discarding geological contacts and assuming uninterrupted heterogeneity throughout the entire modelled hydrolithostratigraphical sequence. A new method had been developed by coupling zonal and pilot point calibration techniques to simulate hydraulic properties heterogeneity in hydrolithostratigraphical units. The new technique to represent aquifer stratification and heterogeneity has global applications and a great potential to assist in making groundwater models more realistic. It could be beneficial to the modellers as well as to the users of the models, including resource managers and regulators.

1.4 Methods and material

The theme of this research is the use of numerical modelling as an integrated framework for developing a defendable understanding of the groundwater system. The research follows a systematic model development process that progresses through a series of interdependent stages with frequent feedback loops to earlier stages as recommended in the Australian groundwater modelling guidelines (Barnett *et al.*, 2012) (Figure 1-1). The model development process is described in detail in Chapter 8.

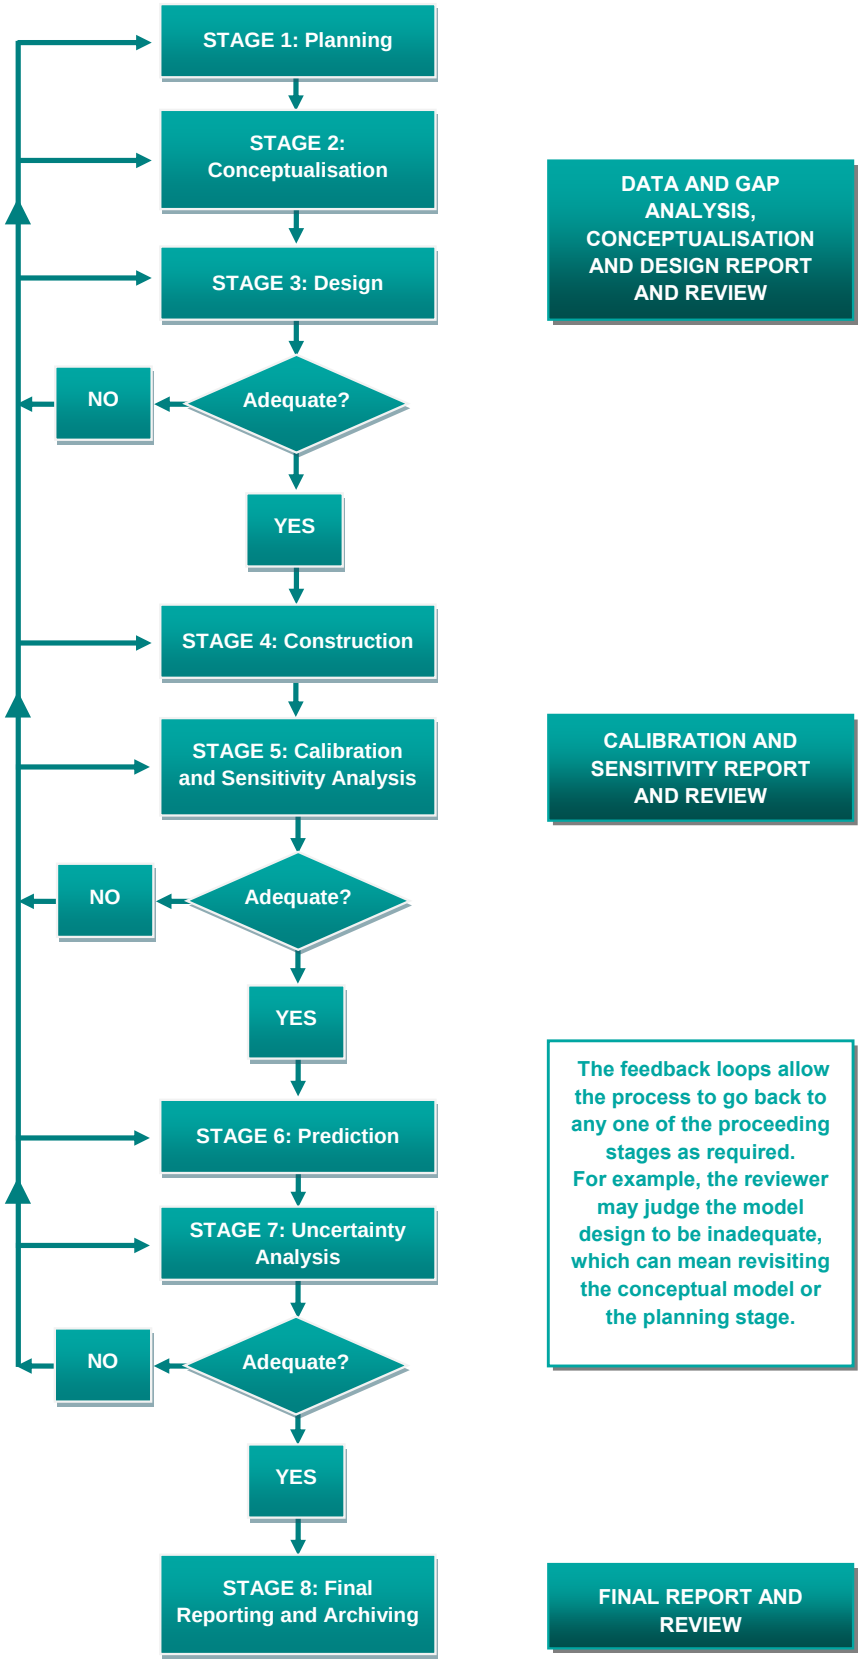

Figure 1-1. Groundwater modelling process (after Barnett *et al.*, 2012).

Numerical groundwater modelling requires vast amounts of data of various types, including information on physiography, soils, geology, climate, hydrology, hydrogeology, hydrochemistry, groundwater abstraction, land cover and use. Often, it is argued that there are not enough data for modelling, but the qualifier 'enough' is subjective. All models are based on available data and knowledge of the modelled system at the time of model development. During their development and use, models can help identify knowledge gaps and guide the collection of further data. Subsequently, models can be improved by incorporating the new acquired data and knowledge. Therefore, groundwater modelling may appear to be a never-ending undertaking. To be practical, however, groundwater modelling starts by identifying the research objective/s and ends by reporting on the process and results.

A good volume of data needed to understand and model the LMC groundwater system has been found to be available. Most of the data used in this research had been obtained from Horizons Regional Council (Horizons)[1], which holds data on wells, drillers' lithology description, groundwater level and quality. Hydrological data are also mainly sourced from Horizons. Geological information was sourced from GNS Science and published work. Climate data were obtained from the National Institute of Water and Atmospheric Research (NIWA) and from their publicly accessible web pages. Data availability and use in this research are described in more detail in relevant chapters.

Limited fieldwork, mainly reconnaissance visits, has been undertaken for this research. The investigation is focused on amalgamating available data to generate new knowledge rather than the generation of new raw data. It identifies data gaps and priorities that need to be addressed by relevant institutions and proposing new methods and techniques to facilitate the development of more realistic geological and hydrogeological models.

[1] Horizons Regional Council (Horizons™) is the trading name of the Manawatu-Wanganui Regional Council, the organisation responsible for managing the natural resources of the Manawatu-Wanganui region, within which the study area is located.

1.5 The study area

The greater Manawatu River catchment straddles the eastern and western flanks of the Ruahine and Tararua axial ranges in the southern North Island of New Zealand. The Manawatu River is antecedent to the Kaikoura Orogeny that formed the ranges and continues to drain water from the Upper Manawatu Catchment (UMC) to the east into the LMC to the west through the Manawatu Gorge. The river ultimately drains into the Tasman Sea. The North Island central ranges effectively separate the groundwater systems in the eastern and western parts of the Manawatu Catchment, albeit allowing surface water flow from the upper catchment to the lower catchment through the Manawatu Gorge. Hence, the LMC can be considered as a separate hydrogeological system from the UMC.

The LMC is part of the Wanganui basin, which is traversed by a series of northeast–southwest trending folds that subdivide it into similarly oriented catchments, including the LMC. The study area is conveniently defined as the Lower Manawatu surface water catchment (Figure 1–2). It includes about 2,678 km² of land area. Based on evidence presented in the following chapters, the surface water catchment and the groundwater catchment are considered coincidental. Notwithstanding, parts of the surface water catchment area have little or no groundwater potential due to the very low permeability of underlying rocks. Consequently, the area of the groundwater resource is smaller than that of the catchment area.

The LMC is drained by the Manawatu River and its tributaries the Oroua River and the Pohangina River. The area can be subdivided into four zones, namely: (1) the Pohangina Valley, (2) the Lower Manawatu Valley (LMV), (3) the Oroua Valley, and (4) the Manawatu Plains. The lower sections of the valleys and the Manawatu Plains form an area with an extensive groundwater resource potential.

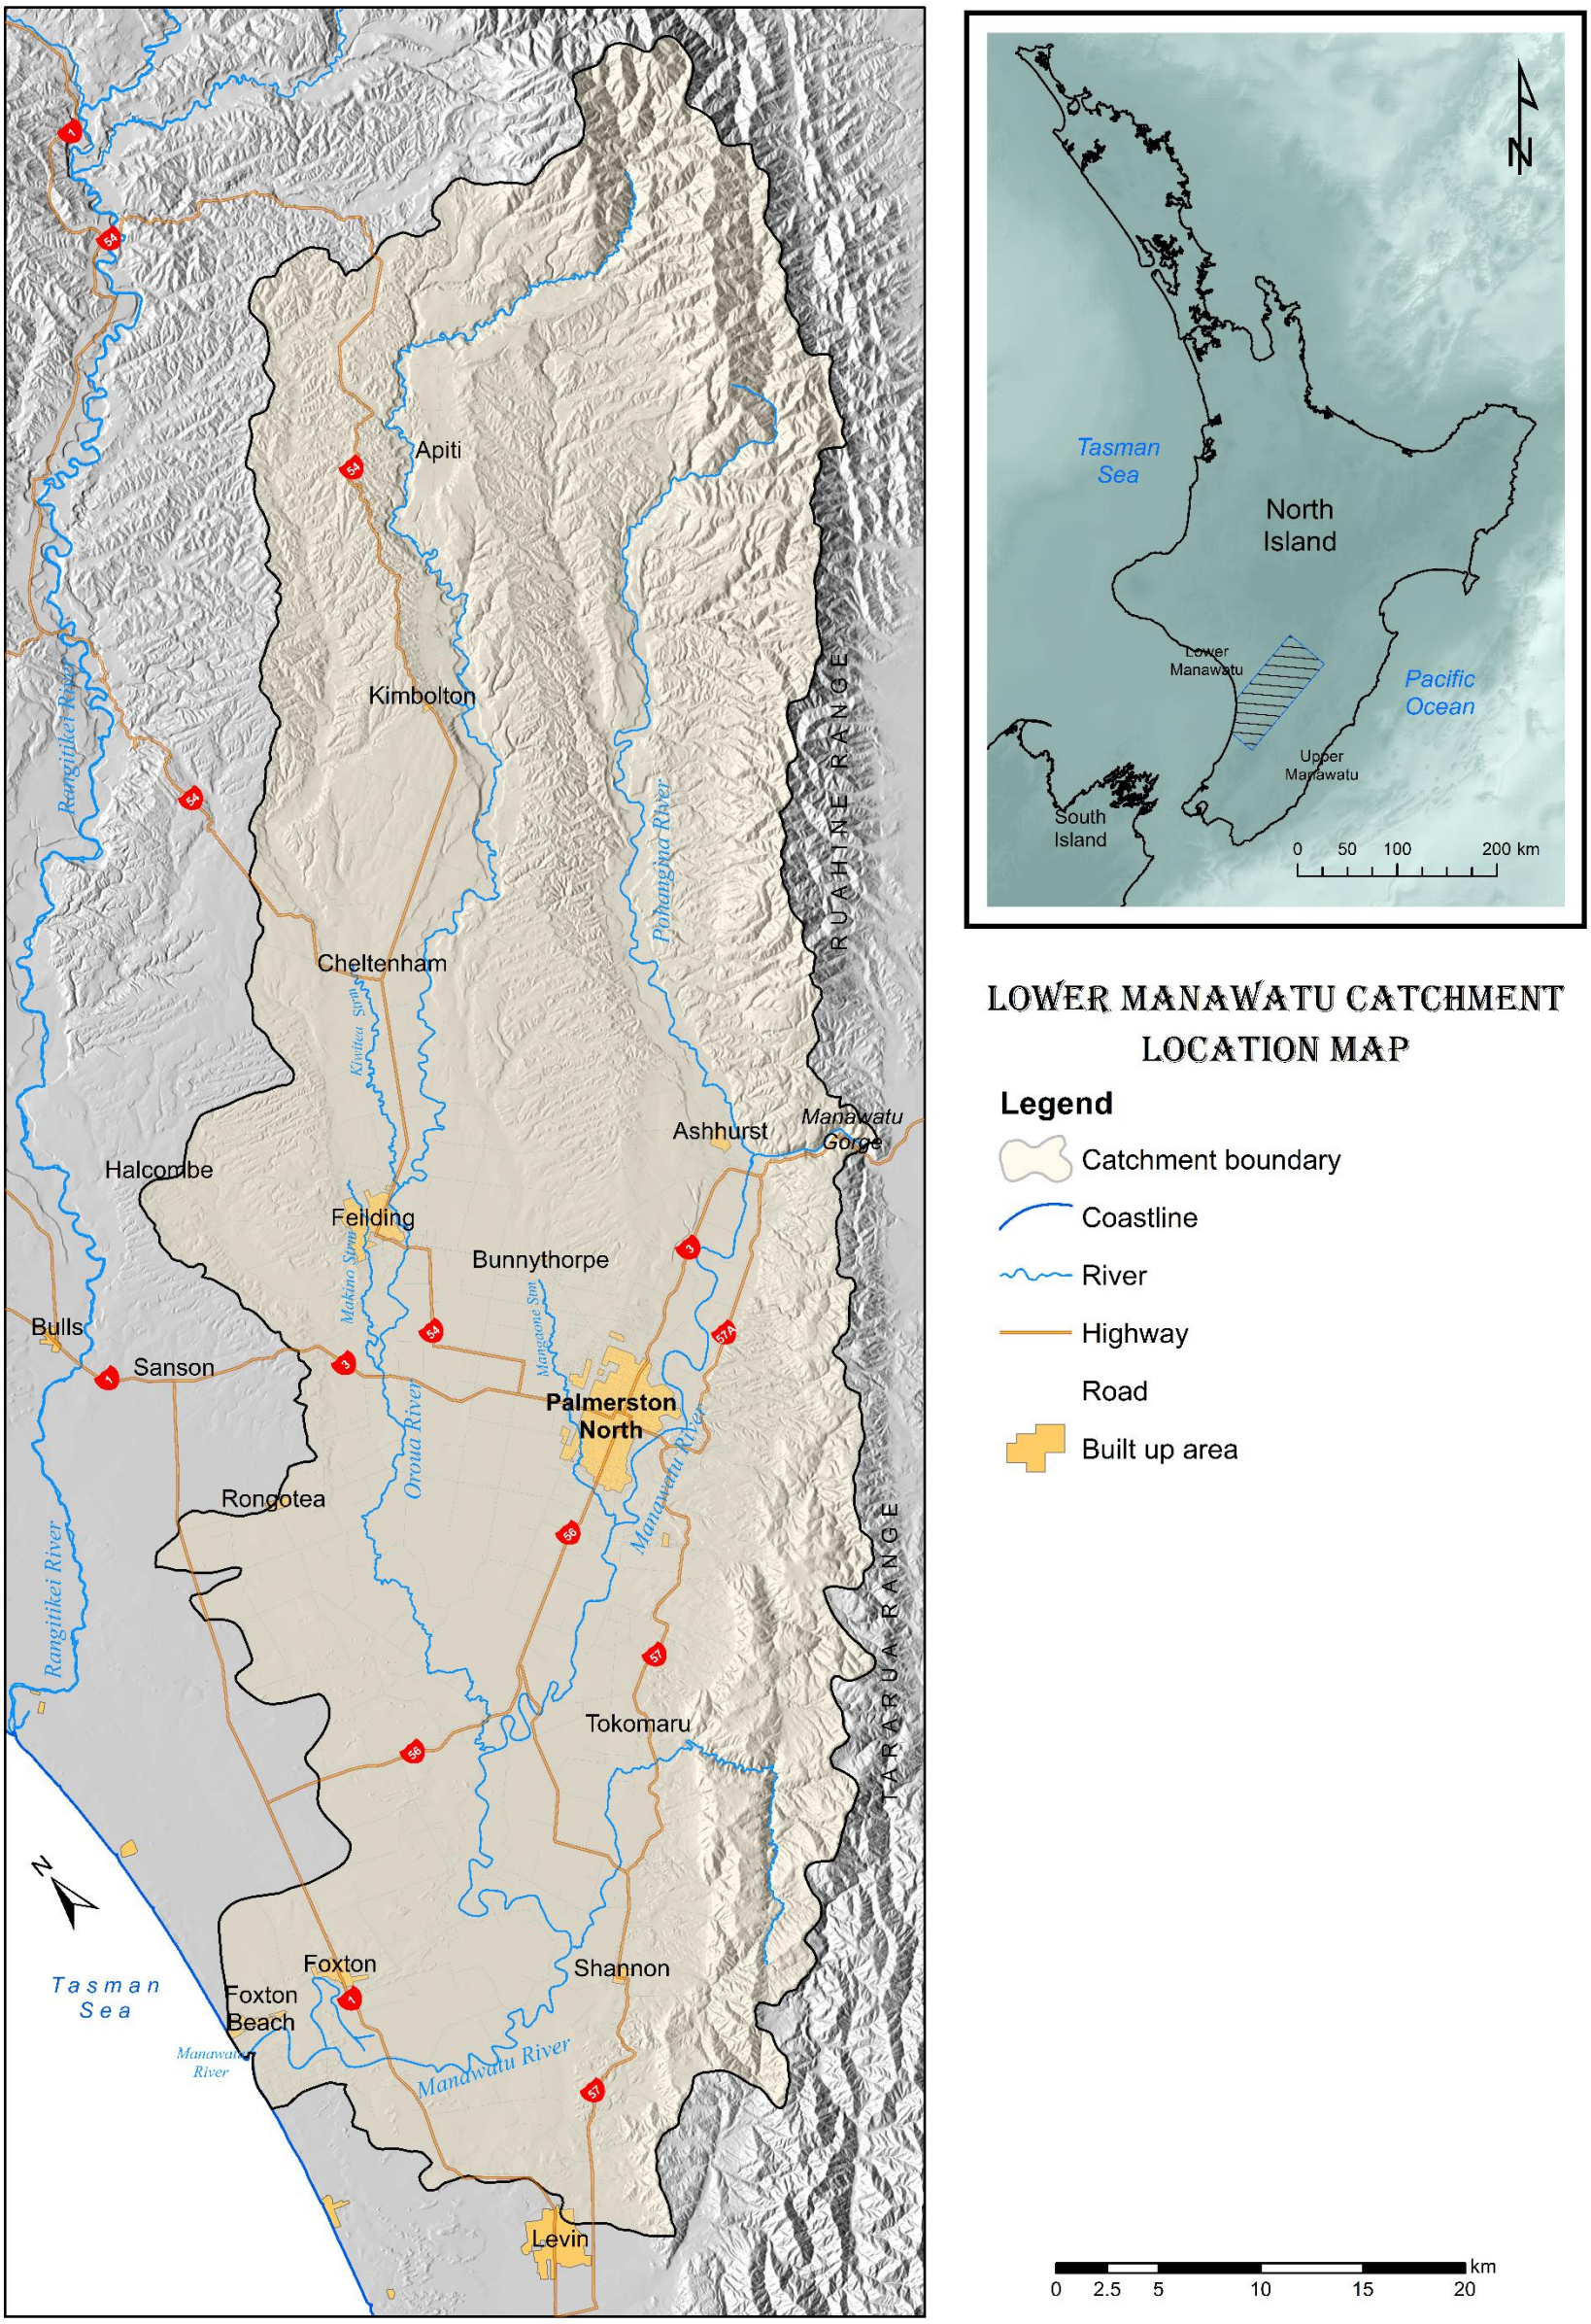

Figure 1-2. Location map showing position, extent and main features in the study area.

The Wanganui Basin contains one of the most complete late Neogene marine stratigraphical records in the world (Carter & Naish, 1998b). The basin depocentre lies c. 20 km to the south of Wanganui and the maximum sedimentary fill thickness is about 4,000 m (Anderton, 1981). In the LMC, the sedimentary sequence maximum thickness is over 1,100 m (Melhuish *et al.*, 1996). However, water wells are normally less than 100 m deep with only few wells exceeding the 200 m depth mark and very few wells in the 300–350 m depth range (Zarour, 2008). Available records provide that the median and average depths of water wells in the LMC are 30 m and 48.75 m, respectively. Accordingly, it has been hypothesised that there is no real hydrogeological interest below 350 m from the ground level. The zone of interest encompasses the entire sedimentary sequence and excludes basement rock, covering c. 2,150 km² of the LMC area. On these bases, the bottoms of the geological and hydrogeological models have been set at the contact between the Late Tertiary–Quaternary sedimentary sequence and the unconformably underlying greywacke basement rock, or 350 m below the ground surface, whichever is shallower.

The horizontal-scale and resolution of the investigation and models are constrained by the scale of the used geological maps (1:250,000) and the groundwater flow model grid spacing (500x500). The vertical resolution of the study is controlled by the model layer thickness (50 m). Hence the information presented in this thesis is usable for large- or catchment- scale purposes and should not be used in site-specific and small-scale interpretations. The study uses and produces average and representative values and the flow models are steady-state, so they cannot be directly used in transient analyses and interpretations. Notwithstanding, subsequent site-specific and transient analyses and models can be effectively based on the findings of this study and the models presented in it.

1.6 Previous work

1.6.1 Hydrogeology

Zarour (2008) summarised earlier groundwater investigations related to the LMC. Not much work has been done since then. Review of previous work reveals

reasonably good understanding of the area's geology. However, this cannot be said about its hydrogeology. So far, the well-developed geological knowledge has not been effectively incorporated in a defensible and agreed conceptual hydrogeological model for the LMC.

Parts of the LMC groundwater resource have been studied but, until now, there has not been a complete study of the resource over the whole catchment. The first known groundwater investigation in the study area is attributed to Marchbanks (1898). He looked at the artesian[2] wells at Longburn, conceptualising them as part of a groundwater flow system that extends up catchment to reach Ashhurst.

Most previous investigators explicitly or implicitly recognised that cyclic lithology related to global glacio-eustasy characterises the geological system in the LMC. As a result, many advocated subdivision of the hydrogeological system in the area into a series of distinct aquifers and aquitards, inaccurately associating groundwater only with cold/glacial times gravel deposits and designating all warm/interglacial periods medium- to fine-grained sediments (mainly sand) as non-water bearing aquitard material (e.g. Martley, 2001). Sand is the dominant lithology beneath the Manawatu Plains. Sand is permeable and generally makes good aquifers (e.g. Fetter, 2013; Freeze & Cherry, 1979; Todd & Mays, 2005). In addition, many investigators confused lithostratigraphical units with hydrolithostratigraphical units (e.g. McCarron & Zarour, 2005) and some misconstrued legitimate, arbitrary mathematical modelling layers as being genuine hydrostratigraphical units (e.g. Gyopari, 2005).

There have been few proposals to subdivide the LMC hydrogeological system into discrete aquifer units based on arbitrary boundaries like depth ranges (e.g. Lieffering, 1990). Such proposals are not useful. Catuneanu (2006) contends that '*the concept of sequence* [such as a hydrogeological system of aquifers and aquitards] *is as good, or acceptable, as the boundaries that define it.*' He further argues that: '*as a matter of principle, it is useless to formalise a unit* [such as an

[2] Old workers tended to describe tube wells as artesian wells.

aquifer] *when the definition of its boundaries is left to the discretion of the individual practitioner.*'

In the Wanganui Basin, structural geology knowledge was mostly not incorporated in delineating the areal extent of groundwater systems (Schumacher, 1999). The interplay of tectonic uplift and glacio-eustatic sea level created terraced valleys in the Wanganui Basin and contributed to its geomorphological development (Fair, 1968). The bearing of tectonism coupled with glacio-eustacism on the area's hydrogeology has been considered by Begg *et al.* (2005) who noted that local-scale deformation has controlled and restricted fluvial erosion, sediment transport and deposition in the area for the last 400 ka[3]. Most of the area's groundwater resource relates to this period – the Haweran Series.

In addition to misunderstanding the real influence of the geology on the area's hydrogeology, many of the previous conceptual models include basic hydrogeological oversight. For instance, Ongley (1945) regarded clay as potential aquifer material because of its high porosity, but he implied that its groundwater yield potential may be restricted because of its low permeability. In doing that, he considered that groundwater resource potential is principally controlled by total porosity rather than permeability, effective porosity and hydraulic conditions.

Upward hydraulic gradient in places in the LMC also proved to be particularly challenging for many previous investigators. Subdividing the system into discrete aquifers and claiming they occur under confined conditions offered a convenient explanation for the artesian conditions noticed in areas in the LMC (e.g. Bekesi, 1991). Such conceptual models failed to appreciate that, by definition, groundwater head increases with depth in discharge zones (e.g. Freeze & Cherry, 1979). They assumed that confining layers provide the only possible explanation for increasing groundwater head with depth. Zarour (2008) noted that evidence from a multi-level piezometer in the LMV suggests a proportional linear relationship between well depth and groundwater head, an indication of hydraulic continuity

[3] ka: thousand years.

rather than abrupt change. The conceptual models of stacked distinct aquifers in the area have not been able to explain the recharge mechanism for the confined aquifers.

The remarkable disagreement amongst the conceptual hydrogeological models presented by various researchers for the LMC represents a serious challenge to environmental authorities and the resource users. Miscorrelation of the geology and hydrogeological of the LMC groundwater system has been costly to the community. For example, many dry wells have been drilled in unsuitable places, including the 181 m deep well drilled by the Kiwitea Rural Water Supply Scheme in 2009. Additionally, many wells across the LMC had to be backfilled to a shallower depth because deeper strata proved unproductive. Flawed hydrogeological conceptualisation may have also contributed to unreliable environmental planning and resource management decisions.

1.6.2 Hydrochemistry

Few investigators studied the groundwater quality in the LMC but none of them focused only on the catchment or covered its entire area. There is still scope and need for specialised and thorough hydrogeochemical investigation of groundwater in the LMC to strengthen the hydrogeological knowledge of the resource.

Marchbanks (1898) considered groundwater quality in his assessment of water wells at Longburn, on the southwestern outskirts of Palmerston North. He reported that at the time the area's groundwater was good, soft, and suitable for use in locomotive boilers. He noted that the water was '*clear, colourless and feebly alkaline water, containing 12.22 gr.*[4] *of fixed salts per gallon. These salts are principally sodic chloride and carbonate and calcic chloride. The proportion of lime in the water is 4.28 gr., and of silica 3.01 gr., per gallon. Only traces of sulphates and magnesia are present. As lime, magnesia, and silica are not present in this water in proportions greater than are here stated, …*'

[4] gr.: grain.

Petricevich (1970) believed that the existence of fresh groundwater in the immediate vicinity of wells in the Palmerston North area and surrounds reflects local recharge. He believed that low chloride (Cl^-) content groundwater flowing from the Tararua Range (direct rainfall recharge) mixes with high Cl^- groundwater near Bunnythorpe to the north of Palmerston North.

Mark-Brown (1978) studied the water quality in Oroua Downs, a coastal area located just to the north of the Manawatu coastal plains. He used the Piper trilinear diagram (Figure 1-3) to classify groundwater quality samples from what he conceptualised as a three-aquifer groundwater system. Figure 1-3 shows that all the samples can be generally typified as calcium-bicarbonate ($Ca^{2+} - HCO_3^-$) water. However, it seems that samples from the shallow wells have higher relative concentrations of Cl^-, which he believed to be related to contamination of shallow groundwater by sea spray. Mark-Brown (1978) noted that groundwater in all the three aquifers that he defined is dominated by alkaline earths as samples plotted in the carbonate hardness area in the Piper diagram. He noted that he did not detect an obvious seasonal pattern in the groundwater quality.

Russell (1989) noticed that groundwater salinity, Cl^- and sodium (Na^+) content increase in the horizontal direction of flow, and that iron (Fe) and fluoride (F^-) concentrations increase with upward flow, resulting in lowered water quality in local and regional discharge areas. He highlighted that ion ratios in groundwater and in the Manawatu River water are similar, but ion concentrations are much higher in the former due to less dilution and longer residence time of water in the aquifers. Russell (1989) hypothesised that the increased salinity noticed in the Manawatu River at low flows is due to the dominance of base flow at such times. He believed that $Na^+ - Cl^-$ water type surficial recharge mixes with upward leaking $Ca^{2+} - HCO_3^-$ water type in the Lower Manawatu Valley area. Russell (1989) found no hydrochemical evidence of separate and distinctive aquifer units in the Manawatu plains and no indications of seawater intrusion in the coastal area.

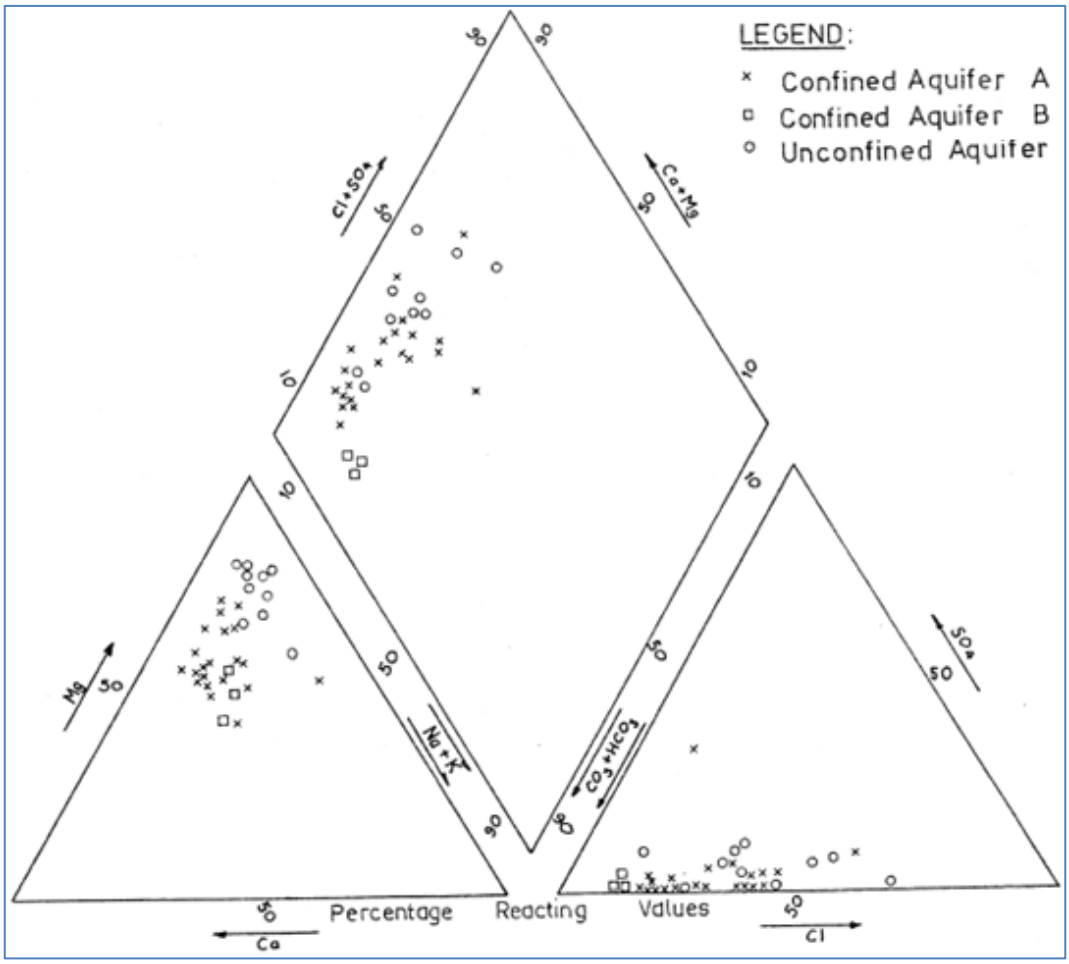

Figure 1-3. Piper trilinear diagram for groundwater samples collected from the Oroua Downs area around 1977 (after Mark-Brown, 1978).

Lieffering (1990) divided the 'Palmerston North region' into five hydrochemical districts but did not provide justification for that. He constructed isoconcentration maps for major constituents and few other parameters. Noticeably, many of his isoconcentration maps show zero concentration isolines, which is unrealistic. Lieffering (1990) found that the groundwater in the Palmerston North area is overall fresh, with total dissolved solids (TDS) generally less than 400 parts per million (ppm). However, higher salinity values reaching around 700 ppm occur to the north of the Oroua River. Lieffering (1990) suggested that the freshest groundwater occurs in the area adjacent to the Manawatu River. He noted that nitrate (NO_3) concentrations in the area are generally very low (<0.2 ppm) but he did not clarify whether that is a measure of nitrate ion (NO_3^-) or nitrate-nitrogen ($NO_3^- - N$)[5]. He

[5] 1 mg/L $NO_3^- - N \approx 4.43$ mg/L NO_3^-.

also noted that Fe concentrations in the area are low (<6 ppm) and manganese (Mn) concentrations are very low (<0.1 ppm). He concluded that in the Palmerston North region groundwater salinity and the concentrations of all parameters except sulphate (SO_4^{2-}) increase from east to west, increase in the direction of flow in the Manawatu River (northeast–southwest), and decrease with depth. He supposed that SO_4^{2-} concentration increases from west to east. Lieffering (1990) tried to relate groundwater quality to the three aquifers that he arbitrary defined at three depth ranges (<60 mbgl[6], 60–120 mbgl, and >120 mbgl). He suggested that higher salinity in the shallow groundwater might be due to increased dissolution of minerals by water flowing upwards from deeper levels. In addition, he suggested that pollution from agricultural land use and sea spray carried inland by westerly winds may be a reason for higher salinity in shallow groundwater in the Palmerston North area.

Bekesi (1991) believed that in the Lower Manawatu Valley, TDS in groundwater increase along the north–northwest flow path. He hypothesised that $Na^+ - HCO_3^-$ water type derived from gravels overlying greywacke basement evolves into $Ca^{2+} - HCO_3^-$ water type along the flow path due to replacement of Na^+ by Ca^{2+} (i.e. reverse ion exchange).

Schumacher (1999) investigated the groundwater quality in the Lower Manawatu Valley. He examined major ion content, their temporal fluctuations, spatial distributions, ratios and oxygen–isotope composition. His trend analysis indicates no significant change in groundwater quality since the onset of groundwater quality monitoring in 1969. He also noticed that seasonal groundwater quality variability is insignificant. His study reveals that Cl^- concentration near the Tararua Ranges is low (<12 ppm) and increases with depth, whereas in the Pohangina area it is relatively high (>45 ppm) and decreases with depth. Schumacher (1999) believed that anthropogenic activities (irrigation and use of fertilisers) are responsible for the relatively elevated Cl^- concentrations at shallow depths in the Pohangina area,

[6] mbgl: metre below ground level.

where agriculture is extensive. He found that salinity (expressed as TDS) in the Lower Manawatu Valley area is generally low and that calcium–magnesium–bicarbonate ($Ca^{2+} - Mg^{2+} - HCO_3^-$) is the dominant water type, which in his opinion is typical of local flow system settings where flow paths are short and flow velocities are high (low residence time). He theorised that $Na^+ - HCO_3^-$ facies results from upwelling of deeper groundwater along fracture zones in the greywacke basement whereas $Ca^{2+} - Mg^{2+} - Cl^- - SO_4^{2-}$ facies possibly reflects leachate from fertiliser application.

Schumacher (1999) looked at oxygen isotopes in groundwater in the Lower Manawatu Valley. He found that delta oxygen–18 ($\delta^{18}O$)[7] is laterally and vertically variable with no systematic distribution, which in his opinion indicates mixing of different recharge waters. He noted that there is no isotopic evidence of groundwater recharge from the Manawatu River to the groundwater system in his study area. He concluded that hydrogeochemical data support hydraulic evidence that recharge at the Pohangina anticline superimposes a local groundwater flow system over the regional groundwater flow system that is controlled by the Tararua Ranges.

Martley (2001) studied groundwater quality in the Feilding area in the Oroua Catchment. She believed that hydrogeochemical typifying in the Feilding area indicates the existence of a shallow local unconfined aquifer exemplified by $Mg^{2+} - Cl^-/Mg^{2+} - HCO_3^-$ water type, which is superimposed on deep confined aquifers that constitute a regional groundwater flow regime in which $Ca^{2+} - HCO_3^-$ water type predominates.

Primarily based on isotope evidence (^{18}O, ^{3}H, ^{13}C and ^{14}C), Taylor *et al.* (2001) defined two confined aquifers underneath an unconfined aquifer in the Palmerston North area. They named the shallower unit the Pohangina aquifer, which they assumed to be recharged on the foothills of the Ruahine Ranges, with groundwater flow in a northeast–southwest direction. They named the deeper confined unit the

[7] Delta oxygen–18 ($\delta^{18}O$) is the ratio of oxygen–18 (^{18}O) to oxygen–16 (^{16}O).

Tararua aquifer, hypothesising that it is recharged on the Tararua Range and that groundwater flows in it in a southeast–northwest direction. They noted that both aquifers are essentially tritium–free (submodern groundwater, recharged prior to 1950s), but only a few of their samples showed conclusive evidence of significant ageing on the ^{14}C timescale.

Based on covert quality parameters, Begg *et al.* (2005) drew a map for the Manawatu–Horowhenua districts that proposes areas of river aquifer recharge, areas of rainfall recharge and areas likely to have unconfined aquifers. The map suggests that in the LMC unconfined groundwater conditions occur in the majority of the area covered with Last Glacial and Holocene material. Begg *et al.* (2005) believed that there is no simple relationship between geology and water quality in their study area.

McCarron and Zarour (2005) noted the existence of very saline, $Na^+ - Cl^-$ water type in a Well 352271, which is drilled in greywacke basement rock in the Poroutawhao area near the groundwater divide between the Manawatu and the Horowhenua areas. They also noted that $Ca^{2+} - Mg^{2+} - HCO_3^-$ groundwater type prevails in the area, with $Ca^{2+} - Mg^{2+} - Cl^- - SO_4^{2-}$ in limited locations. They believed that groundwater quality in the area reflects heterogeneity and anisotropy of the aquifer system more than expressing hydrogeological relationships and characteristics. They noted that they found no evidence on seawater invasion in the coastal area.

Zarour (2008) reported that only about 30% of the hydrochemical data in the regional groundwater database has acceptable cation–anion balance (see Section 7.5). He maintained that long–term hydrogeochemical monitoring data do not exhibit noteworthy seasonal variability or long–term trends. Zarour (2008) confirmed that $Ca^{2+} - Mg^{2+} - HCO_3^-$ water type predominates in the area. He did not see distinct hydrochemical facies distribution and he considered that to be an indication of the absence of discrete separate aquifers. Zarour (2008) noted that mineral dissolution and ion exchange are the dominant processes controlling

groundwater quality evolution in the area. He found no indication of mixing of fresh groundwater with saline seawater in the coastal section of the study area. Zarour (2008) believed that the area's groundwater generally meets potable standards and that it is generally suitable for irrigation, with low to medium salinity hazard and low sodium hazard.

Daughney *et al.* (2009) undertook statistical analysis of available hydrochemical data in the Horizons region. They employed Hierarchical Cluster Analysis (HCA) techniques to define distinct groundwater quality 'categories' and partition monitoring sites amongst them. They found that available data allow for a high level of hydrogeochemical interpretation but noted that limitations in the length and continuity of data for most monitoring sites make it difficult to assess trends in groundwater quality in the area. For the few sites that they found to have sufficient data, they perceived that groundwater quality is not changing substantially over time. They found no evidence of seawater intrusion into the coastal aquifer and only very few wells that have NO_3^- concentrations that exceed the expected natural background. Hence, Daughney *et al.* (2009) concluded that there is not much detectable influence of human activities on the area's groundwater. They contended that spatial groundwater quality variations across the area reflect differences in the origin and type of materials comprising the various aquifers. They highlight that most of the area's groundwater is oxygen-poor due to natural chemical and biological reactions that take place as water flows under the ground. They explain that these processes result in accumulation of dissolved Fe, Mn and ammonium (NH_4^+), alongside the depletion of NO_3^- and, sometimes, SO_4^{2-} in the groundwater, a pattern that they observed across much of the Wanganui Basin. They suspected that naturally occurring high levels of Fe, Mn, NH_4^+, hardness and pH may slightly impair groundwater usability for human consumption and irrigation.

Zarour *et al.* (2011) reported on Horizons Regional Council's groundwater monitoring activities, including groundwater quality. Their report clarifies that the main purpose of Horizons groundwater quality monitoring is meeting their statutory responsibilities. The report provides a clear account of what parameters and sites

are being monitored. The report does not deal with non-programme groundwater quality monitoring, but this thesis utilises data from both non-programme and one-off sources to provide the maximum possible spatial coverage for hydrochemical interpolation purposes.

PDP (2013a) undertook a review of Horizons Regional Council's groundwater quality data and monitoring network. They noticed a gap in the data between late 2002 and 2005 as only few parameters from few wells have been recorded during that period. PDP (2013a) confirmed that $Ca^{2+} - HCO_3^-$ water quality type dominates the groundwater system in the area and that reduced conditions prevail. They argue that salinity increases with depth in the region, but the data they present do not support that opinion, which is contrary to all previous work. They maintained that salinity as indicted by electrical conductivity (EC) increases near the coastal area to the north of the Manawatu River due to longer flow paths. They also noticed high EC in a well near the confluence of the Manawatu River with the Pohangina River and relatively high Cl^- in a well in the coastal area and two wells in the Pohangina Catchment. The shallow well with high Cl^- near the Manawatu River-Pohangina River confluence also had elevated *E. coli*, possibly a reflection of contamination from nearby land use activities.

PDP (2013b) undertook a review of the seawater intrusion monitoring network in the Manawatu-Wanganui region. There are no seawater intrusion monitoring wells in the LMC. However, seawater intrusion is monitored in Well 332009 (25 m deep) located about 10 km to the north of the LMC in the Rangitikei plains and Well 352312 (86 m deep) located about 5 km to the south of the LMC in the Horowhenua plains. The construction details, including screen length and position are unknown for both wells. PDP (2013b) review of the seawater intrusion monitoring network revealed that there is no evidence of seawater invasion into the aquifers in the coastal area in the Manawatu-Wanganui region and assessed the risk of seawater intrusion in that area to be low. The review indicated that groundwater quality at the coast is not significantly different to that seen inland, especially in terms of ion ratios. The study showed that EC and Cl^- concentration in the two monitored wells near the

study area are relatively low (c. 550 µS/cm and c. 20–40 mg/L, respectively). PDP (2013b) also found no obvious trend of increasing Cl^- or EC with depth in coastal monitoring bores. They noted that salinity can increase or decrease during pumping. In their opinion, an increase in salinity with pumping can mean drawing saltier water towards the pumped well whereas salinity reduction with pumping can mean inducing flow of fresher water towards the well because of pumping or that water in the well was stagnant and the well water's salinity is reduced with the removal of stagnant, relatively more saline water.

Overall, the following general characteristics of the LMC groundwater system can be deducted from previous hydrochemical investigations:

1. ion-ratios in groundwater and surface water are similar, but content concentrations are higher in groundwater
2. groundwater quality is generally good in the LMC, making it suitable for many beneficial purposes
3. groundwater quality has not changed much since the start of monitoring in 1969, and possibly over the last 120 years since the study by Marchbanks in 1898
4. groundwater quality seasonal variability is very small
5. there is no evidence of anthropogenic influence over groundwater quality in the area, including salinity levels and nitrate concentrations
6. there is no indication of seawater invasion into the coastal part of the groundwater system
7. discharge settings dominate in the lower part of the LMC, i.e. groundwater provides baseflow in low surface water flow conditions and gains no water from surface waterways in the area
8. groundwater salinity and major ion content increase along flow direction from northeast to southwest and decrease with depth
9. there is no evidence of distinct aquifers or special areal groundwater quality domains within the groundwater flow system in the LMC

10. there is need for additional isotope and age determination investigations to help understand recharge and flow mechanisms.

1.7 Thesis organisation

This chapter presents an introduction to the thesis, portraying the importance of groundwater in the study area, outlines the research problem and objectives, new contribution to knowledge and science, and describes the research methodology and material. It provides a general description of the LMC and critically reviews literature relevant to its groundwater resource. Chapter 2 presents methodological background for groundwater flow modelling and clarifies the basis for selecting the adopted approach, code and software for modelling the LMC groundwater system. Chapter 3 describes the physiography, soil and geology of the area, providing a general framework for further lithological interpretation. Chapter 4 discusses the area's climate and presents a soil moisture balance model to calculate various components of the hydrological cycle, including groundwater recharge. Chapter 5 summarises the area's hydrology to help recognise the relationships between surface water and groundwater in the area. Chapter 6 draws the hydrogeological scene, including identification of hydrolithostratigraphical units as basis for hydrogeological conceptualisation, discusses aquifer properties and sets out the groundwater flow system picture including variability of hydraulic head in space and time, flow directions, and hydraulic gradients. To complement hydrogeological characterisation, Chapter 7 extracts evidence from groundwater quality data, depicting processes controlling groundwater quality and clarifying groundwater quality issues relating to various uses. Chapter 8 is dedicated to presenting the modelling process and results. Chapter 9 presents the investigation's conclusions, discusses the main findings and makes recommendations for further work. Cited references are listed at the end of the thesis followed by appendices that contain selected used datasets and model calculation results.

Chapter 2 Groundwater modelling methodology

2.1 Introduction

Characteristics and historical behaviour of groundwater systems can be deduced through investigations and examination of past records, where 'real' data can be analysed to decipher how static and changing natural and anthropogenic influences resulted in the current hydrogeological situation. However, assessing future behaviour of aquifers under various resource management scenarios and/or changing natural conditions requires subjecting the aquifer to the anticipated stresses and allowing time for the aquifer to react, which is virtually unattainable. Realistically, the only practical option is to simulate the groundwater system and study its response to anticipated conditions to advise resource management planning and decision making (Thangarajan, 2007). To achieve this, an operational groundwater model is needed (Mercer & Faust, 1980).

2.1.1 Fitness for purpose

In general terms, a model is a representation of an object, a subject or a system. Models emulate fundamental characteristics of items or themes but ignore insignificant traits. Similarly, simulations embody only essential aspects of real-life conditions and omit trivial factors. Models are useful to understand things we cannot see, find out how things work, find solutions to confounding problems, and expressing and communicating thoughts. They can be presented in the form of physical objects, words, equations, images, schematic diagrams, animated multi-media, or any combination of the above depending on the nature of the modelled subject, purpose of the model, the target recipients, available technology, time and resources.

Box and Draper (1987) theorise that because models are approximations, essentially, they all '*are wrong, but some are useful.*' However, they also argue that the fact that although the polynomial is an approximation does not necessarily detract from its usefulness. So, they articulate that '*… the practical question is how*

wrong do they [models] *have to be to not be useful?*' Posters in the Boston Museum of Science seen by the author in September 2012 advocate that models must be assessed only for how they fit their purposes and that whether a model is good or bad entirely depends on how well it serves its intended use. Hence, the foremost and most important step in any modelling work is to determine clearly the model objectives so that its fitness for purpose can be objectively assessed (e.g. Anderson & Woessner, 2002; Barnett *et al.*, 2012; Younger, 2007).

2.1.2 Understanding through modelling

Most commonly, groundwater modelling objectives are focused on the quantitative assessment of the response of heads, flows or solute concentrations to future stresses on the groundwater system. However, important modelling objectives include gaining insight into the processes that are important under certain conditions (i.e. analysing sensitivities), identification of knowledge gaps and informing where additional effort should be focused to gather further information (Barnett *et al.*, 2012).

Quantitative groundwater modelling has become an essential tool in hydrogeological investigations and assessments. It is now widely accepted that modelling is a useful reality check to test our understanding of hydrogeological systems. Lichtner (1996) upholds that '*Quantitative models force the investigator to validate or invalidate ideas by putting real numbers into an often vague hypothesis and thereby starting the thought process along a path that may result in acceptance, rejection, or modification of the original hypothesis.*' Therefore, many conferences and special journal issues have been focused on the theme of understanding groundwater systems through modelling (Zheng *et al.*, 2006).

2.1.3 Limitations and challenges

Non-uniqueness in models presents a particularly important challenge. It means that many different combinations of model inputs produce results that match measured data. Consequently, there will always be more than one possible reasonable model (Anderson *et al.*, 2015). Non-uniqueness of groundwater

models is particularly noteworthy in inverse modelling, the process during which the model is attempted to be calibrated to real-life observations. Inverse modelling may, at times, result in meaningless solutions (Carrera & Neuman, 1986), so sensibility and reality checks are needed. Yeh *et al.* (2015) believe that inherent inverse modelling shortcomings can be mitigated through increased model parameterisation. In reality, it is impossible to produce a unique representative model of a groundwater system. In addition, every model is based on data and assumptions that contain some degree of uncertainty (Merry *et al.*, 2003). Uncertainty in groundwater models arises from a number of factors related to representing groundwater processes. During various stages of modelling, the modeller makes subjective choices (code to use, important processes, datasets trustworthiness, etc.) that honour or discount various attributes of the modelled system to various degrees. Ignorance of one or more important parameters represents another dimension of uncertainty (Hunt & Welter, 2010). Obviously, the unknowns can only be left out of models. Overall, modelling uncertainty can only be reduced, never eliminated (Anderson *et al.*, 2015).

Modelling limitations such as simplifying assumptions, field-data quality, non-uniqueness and uncertainties must be recognised and acknowledged in all groundwater models (e.g. Anderson & Woessner, 2002; Doherty & Hunt, 2010; Hill & Tiedeman, 2007; Mercer & Faust, 1980; PDP, 2002; Sreekanth *et al.*, 2015). Typically, these issues are addressed by evaluating the sensitivity of model predictions to changes in model conceptualisation or input. Failing to assess and communicate model limitations is considered modelling misuse. This is commonly unintentional, stemming from the modeller's lack of knowledge. However, it could also be deliberate.

2.2 Flow in porous media

The aquifer system in the LMC consists predominantly of loose to poorly-cemented Quaternary clastic sediments. Groundwater flows in such material mostly through pores. Groundwater flow through porous media is quantitatively described by Darcy's law.

2.2.1 Darcy's law

In 1856, Henry Darcy developed an empirical equation to describe flow of fluid through porous media from extensive work on the flow of water through sand filter beds (e.g. Bennett, 1989; Fetter, 2013; Freeze & Cherry, 1979; Kruseman & de Ridder, 1991). Figure 2-1 schematically represents Darcy's experimental apparatus.

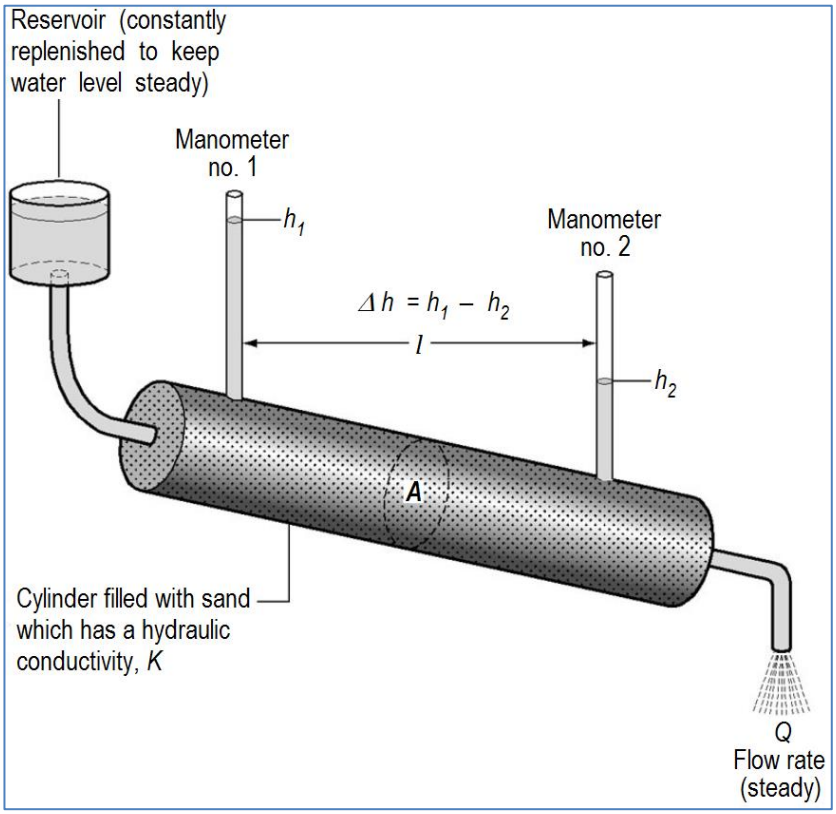

Figure 2-1. Schematic represent of Darcy's experimental apparatus illustrating the terms in Darcy's Law (after Younger, 2007).

Darcy noticed that steady flow per unit area (q), termed specific discharge or Darcy flux, is directly proportional to the hydraulic gradient over the flow distance, i.e.

$$q = \frac{Q}{A} \propto \frac{\Delta h}{l} \qquad 2\text{-}1$$

where Q represents the volumetric flow rate of the fluid downward through the cylindrical sand pack of cross-sectional area A and length l, and Δh is the difference between the hydraulic head above the standard datum of the water in the manometers located at the input and output ports (h_1 and h_2, respectively).

Conveniently, hydraulic gradient (i) is defined as $\Delta h / l$. Hence, Equation 2-1 can be written as:

$$\frac{Q}{A} \propto i \qquad 2\text{-}2$$

Darcy assigned a proportionality constant (K), which represents the ability of the porous media to allow flow through it. In general terms, K is a 'coefficient of permeability'. In the case of water, K is termed 'hydraulic conductivity'. In contemporary format, using a particular sign convention, Darcy's equation (law) is usually written as:

$$Q = K\, i\, A \qquad 2\text{-}3$$

2.2.2 Reynolds number

Kruseman and de Ridder (1991) clarify that Darcy's law (Equation 2-3) is valid for laminar flow, but not for turbulent flow, as the case may be in cavernous or fractured rocks. Reynolds number (N_R) is a criterion to distinguish between laminar and turbulent flow. It is expressed as:

$$N_R = \rho \frac{qd}{\mu} \qquad 2\text{-}4$$

where ρ is the fluid density, q is the specific discharge, μ is the viscosity of the fluid, and d is a representative length dimension of the porous medium, usually taken as effective grain-size diameter (D_{10}), or mean pore diameter. Theoretically, Darcy's law is valid for $N_R < 1$ but in reality no serious errors are created up to $N_R = 10$. Fortunately, most groundwater flow occurs with $N_R < 1$, so that Darcy's law applies (Kruseman & de Ridder, 1991). Kruseman and de Ridder (1991) indicate that the relation between q and the hydraulic gradient (i) is not linear for low i values, invalidating Darcy's law. Such circumstances could be encountered for example in compact clays. However, they note that it is impossible to give a unique lower limit to the hydraulic gradients at which Darcy's law is still valid because the

values of i vary with the type and structure of the clay, while the mineral content of the water also plays a role.

2.3 Groundwater flow governing equations

Using a cubical representative fixed control volume element (RFCVE) as shown in Figure 2-2, a mass balance can be established as:

$$Q_{in} - Q_{out} = \frac{\Delta M}{\Delta t} \qquad 2\text{-}5$$

where Q_{in} is total inflow, Q_{out} is total outflow, ΔM is change in mass over a specific time period (Δt).

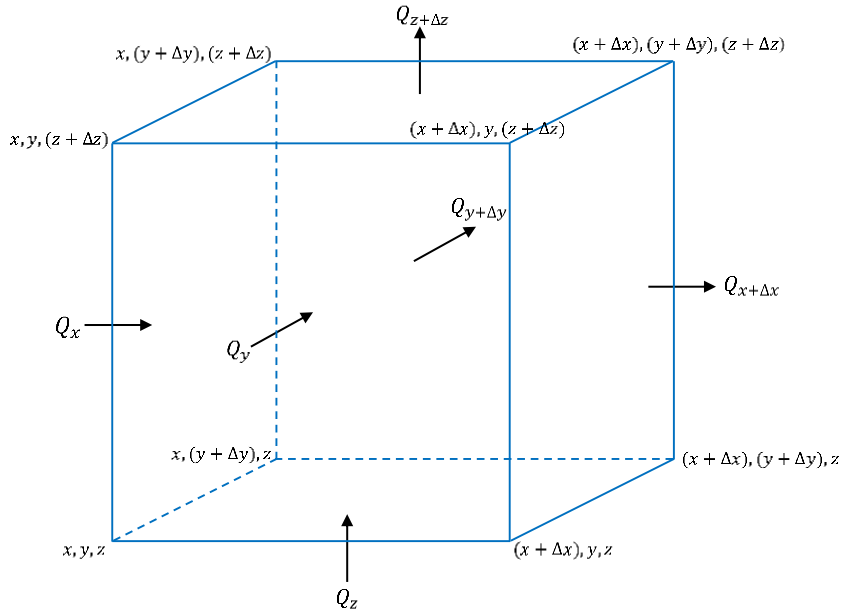

Figure 2-2. Schematic illustration of mass balance for a representative fixed control volume element (RFCVE).

Darcy's law is a phenomenological law or constituitive equation. Hence, it can be combined with the conservation equation to provide 3D mass balance. Using Figure 2-2 notation, Equation 2-5 can be written as:

$$[Q_x - Q_{x+\Delta x}] + [Q_y - Q_{y+\Delta y}] + [Q_z - Q_{z+\Delta z}] = S_s \frac{\Delta h}{\Delta t} \qquad 2\text{-}6$$

where S_s is the specific storage coefficient, defined as the volume of water released from storage (ΔV_W) per unit change in head per unit volume, i.e.

$$S_s = \frac{\Delta V_W}{\Delta h\, \Delta x\, \Delta y\, \Delta z} \qquad 2\text{-}7$$

Axes for the RFCVE (Figure 2-2) are selected in the principal directions of permeability (directions of maximum and minimum permeabilities for the x and z directions, respectively).

Using Darcy's law terms (Equation 2-3) and making Δt very small, Equation 2-6 can be written as:

$$\frac{\partial}{\partial x}\left(K_x \frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y \frac{\partial h}{\partial y}\right) + \frac{\partial}{\partial z}\left(K_z \frac{\partial h}{\partial z}\right) = S_s \frac{\partial h}{\partial t} - R^* \qquad 2\text{-}8$$

Equation 2-8 is the governing equation of groundwater flow in 3D. It includes a general source/sink term (R^*) that can be used to represent additional inputs (e.g. recharge) and outputs (e.g. pumping). R^* is a positive value for inputs and negative for outputs.

Application of the governing equations to real-life situations requires the definition of boundary and initial conditions (Igboekwe & Achi, 2011).

2.3.1 Laplace equation

Under isotropic ($K_x = K_y = K_z$), homogeneous ($K_1 = K_2 = \ldots = K_n$) aquifer conditions and steady-state flow conditions[8], Equation 2-8 can be reduced to Equation 2-9, which is a Laplace equation.

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} + \frac{\partial^2 h}{\partial z^2} = 0 \qquad 2\text{-}9$$

[8] Steady-state flow is flow in which all conditions (velocity, pressure, etc.) remain constant with respect to time.

2.3.2 Unconfined aquifers

For unconfined aquifer conditions (Dupuit–Forchheimer assumption; horizontal flow that is proportional to the saturated aquifer thickness), it is standard practice to assume that $T_x = K_x h$ and $T_y = K_y h$ where h is assumed to be equal to b, the aquifer saturated thickness (Anderson & Woessner, 2002). Under these conditions, the groundwater flow governing equation takes the following form (the Boussinesq equation):

$$\frac{\partial}{\partial x}\left(K_x h \frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y h \frac{\partial h}{\partial y}\right) = S_y \frac{\partial h}{\partial t} - R^* \qquad 2\text{–}10$$

where S_y is the specific yield. By realising that

$$\frac{\partial h^2}{\partial x} = 2h \frac{\partial h}{\partial x} \qquad 2\text{–}11$$

$$\frac{\partial h^2}{\partial y} = 2h \frac{\partial h}{\partial y} \qquad 2\text{–}12$$

Equation 2–10 can be rewritten as:

$$\frac{\partial}{\partial x}\left(K_x \frac{\partial h^2}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y \frac{\partial h^2}{\partial y}\right) = 2S_y \frac{\partial h}{\partial t} - 2R^* \qquad 2\text{–}13$$

2.4 Analytical solutions

Analytical solutions, also known as closed form solutions, use symbolic manipulation techniques to solve mathematical problems and evaluate the unknown variable. The famous Thiem (1906) equation (Eq. 2–14) and the Theis (1935) equation (Eq. 2–15) for flow in homogeneous, isotropic, confined aquifers under steady–state and unsteady–state conditions, respectively, are examples of analytical solutions.

$$Q = \frac{2\pi T(s_{m1} - s_{m2})}{2.30\ log(r_2/r_1)} \qquad 2\text{-}14$$

where Q is the well discharge, T is the aquifer transmissivity ($T = Kb$), r_1 and r_2 are the respective distances of the piezometers from the pumped well, s_{m1} and s_{m2} are the respective steady-state drawdowns in the piezometers.

$$s = \frac{Q}{4\pi T} \int_u^\infty \frac{e^{-y}\,\mathrm{dy}}{y} = \frac{Q}{4\pi T} W(u) \qquad 2\text{-}15$$

Where s is the drawdown in a piezometer at a distance r from the pumped well, Q is the well discharge, T is the transmissivity of the aquifer, $u = r^2S/4Tt$, S is the dimensionless storativity of the aquifer, t is time since pumping started, and the well function of u is defined as:

$$W(u) = -0.5772 - ln\,u + u - \frac{u^2}{2.2!} + \frac{u^3}{3.3!} + \frac{u^4}{4.4!} + \cdots \qquad 2\text{-}16$$

According to Perina (2010), the governing formula for the Theis equation (Eq. 2-15) is:

$$\frac{\partial^2 s}{\partial r^2} + \frac{1}{r}\frac{\partial s}{\partial r} = \frac{S}{T}\frac{\partial s}{dt} \qquad 2\text{-}17$$

The boundary conditions are:

$$s \to 0 \text{ for } r \to \infty,\ t \geq 0 \qquad 2\text{-}18$$

and

$$-2\pi r T \frac{\partial s}{\partial r} = Q \text{ for } r \to \infty,\ t \geq 0 \qquad 2\text{-}19$$

and the initial condition is:

$$s = 0 \text{ for } t = 0 \qquad 2\text{-}20$$

where $s(r,t)$ is the drawdown, r is the radial distance from the pumping well, t is the time since pumping started, Q is the constant extraction rate, T is transmissivity, and S is storativity.

Analytical methods use simplifying assumptions to provide an exact solution for every point in space and/or time uniformly over the model domain. For example, given abstraction rate and transmissivity, we can use the Thiem (1906) equation (Eq. 2-14) to calculate drawdown at various distances from a pumped well in a homogeneous, isotropic, confined aquifer under steady-state flow conditions. We can also evaluate transmissivity given abstraction rate, distances to observation points and drawdown at them (e.g. to evaluate T from pumping test data).

Analytical solutions are well suited for simplified problems. To a certain degree, real-life complexity can be dealt with analytical solutions through the application of the principle of superposition to scalar potentials and velocity vectors (Reilly *et al.*, 1984), introducing terms to represent processes such as recharge and/or manipulating boundary conditions. Nevertheless, it is impossible to use analytical methods to account for variations in field conditions that occur with time and space because of their inherent simplicity. For situations where it is important to account for spatial and temporal variations in hydraulic properties and conditions, the assumptions to be made to obtain an analytical solution will not be realistic. Approximation using numerical solution techniques is obligatory in such situations to solve the governing equation satisfactorily under the given boundary, initial and operational conditions.

2.5 Numerical solutions

Numerical methods are not intended to calculate an exact solution for the groundwater flow governing partial differential equation (PDE; Eq. 2-8), but they

are formulated to obtain a reasonable approximate solution (Anderson *et al.*, 2015; Thangarajan, 2007). Unlike analytical solutions, numerical solutions are not continuous in space or time. They calculate head at discrete points (nodes) in space and for specified values of time (stress periods and time steps within them). This allows numerical models to be used in full transient, 3D simulations of heterogeneous, anisotropic aquifers under complex boundary and initial conditions.

Finite difference (FD) and finite element (FE) methods are the most commonly used approximation methods to solve the PDE. It has been shown that both FD and FE formulations of the Laplace equation (Eq. 2-9) and even more complex versions of the PDE produce the same set of algebraic equations and the same results if nodal spacing is sufficiently small (e.g. Pinder & Gray, 1976; H. F. Wang & Anderson, 1977, 1982).

2.5.1 Finite difference methods

By introducing transmissivity ($T = Kb$) and storativity ($S = S_s b$) to the general groundwater flow governing equation (Eq. 2-8), one-dimensional (1D) flow in isotropic media can be expressed as follows:

$$\frac{\delta^2 h}{\delta x^2} T = S \frac{\delta h}{\delta t} - R^* \qquad 2\text{-}21$$

Because h appears to the second power on the left-hand side of the equation and to the first power on its right-hand side, Eq. 2-21 is nonlinear (Figure 2-3). However, it can be effectively linearised in a numerical model by using the current (known) value of the saturated thickness (b), which is the approach used in many modelling packages, including MODFLOW (Anderson & Woessner, 2002).

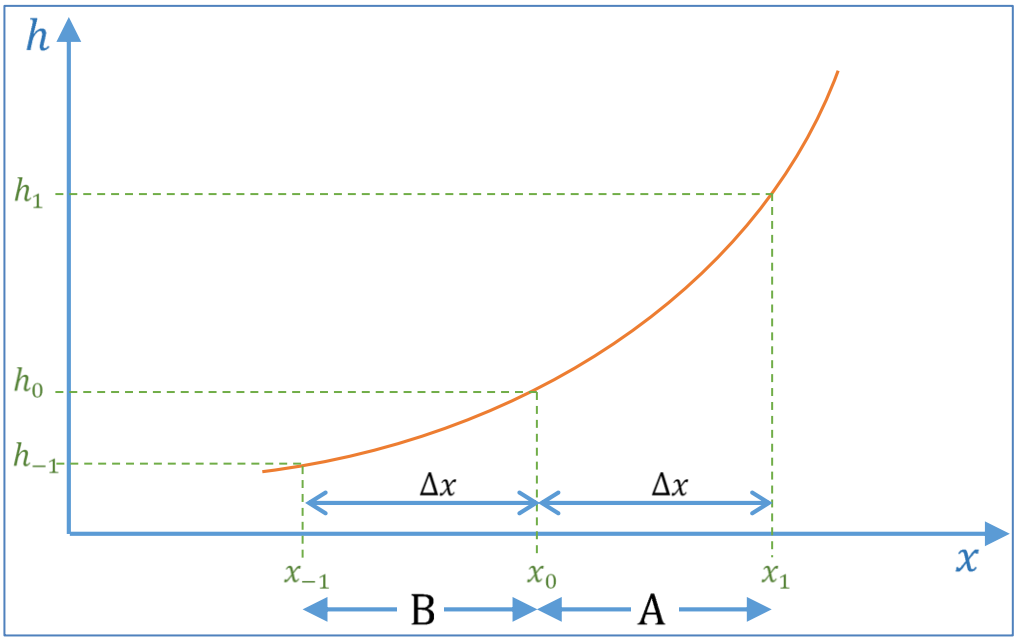

Figure 2-3. Graphical illustration of approximation used to linearise Eq. 2-21.

Solving Eq. 2-21 requires approximation of the term $\frac{\delta^2 h}{\delta x^2}$. If we divide space in the x direction into equal segments (Δx) as illustrated in Figure 2-3, the change in hydraulic head for segments A and B can be expressed as follows:

$$\left(\frac{dh}{dx}\right)_A = \frac{h_1 - h_0}{\Delta x} \qquad 2\text{-}22$$

and

$$\left(\frac{dh}{dx}\right)_B = \frac{h_0 - h_{-1}}{\Delta x} \qquad 2\text{-}23$$

The difference in hydraulic gradient over segments A and B can be written as:

$$\frac{d}{dx}\left(\frac{dh}{dx}\right) = \frac{\left(\frac{dh}{dx}\right)_A - \left(\frac{dh}{dx}\right)_B}{\Delta x} \qquad 2\text{-}24$$

By substituting equations 2-22 and 2-23 into Eq. 2-24 and simplifying, we get:

$$\frac{\delta^2 h}{\delta x^2} = \frac{h_1 - 2h_0 + h_{-1}}{\Delta x^2} \qquad 2\text{–}25$$

So, we can write the differential equation for steady-state as:

$$h_1 - 2h_0 + h_{-1} = \frac{-R^* \Delta x^2}{T} \qquad 2\text{–}26$$

The same approach can be followed to produce differential equations in the y and z directions. Given initial conditions and boundary conditions, equations like Eq. 2–26 can be solved numerically. This approach is known as the finite difference (FD) method.

In the FD method, a continuous medium is subdivided into cuboidal RFCVEs similar to the one shown in Figure 2–2 and relevant hydrogeological parameters are assigned to nodes positioned at RFCVE centres (Figure 2–4). Relative positions of nodes within the grid are assigned using i, j, k indices representing column, raw and layer, respectively[9]. Difference operators defining the spatial-temporal relationships between various parameters replace the partial derivatives, giving a set of finite difference equations, one for each node. Solving the finite difference equations starts with the initial distribution of heads to compute heads at later time instants. Heads are defined and calculated only at nodes and the head at a node represents the average head in the FD cell. Fast converging iterative algorithms have been developed to solve the set of algebraic equations obtained through discretisation of the PDE (Thangarajan, 2007).

[9] Sometimes a different indexing convention is used. For example, in MODFLOW i = rows and j = columns.

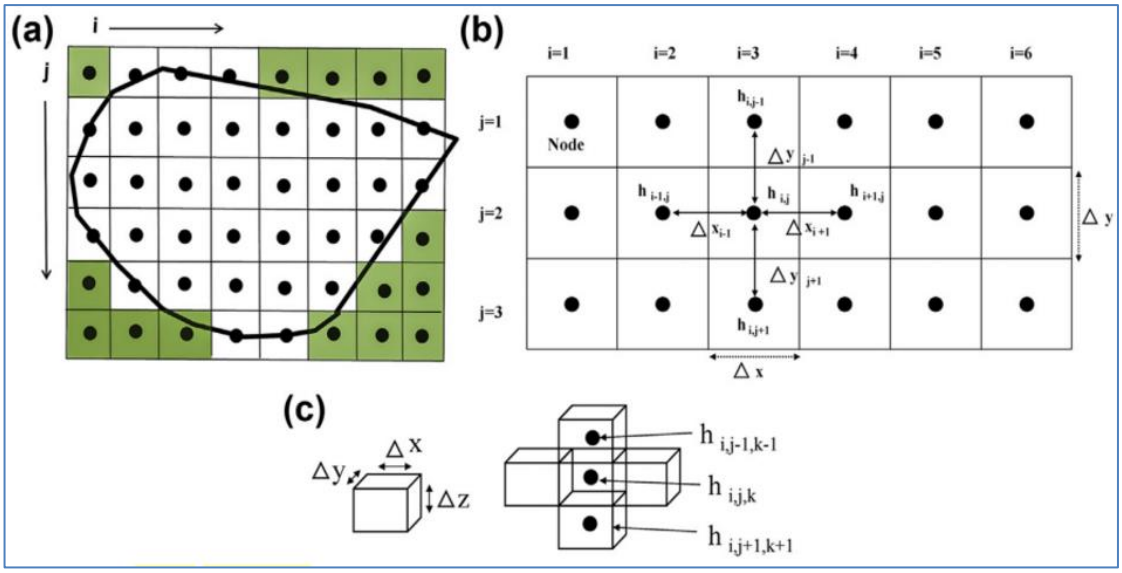

Figure 2-4. Finite-difference (FD) grid and notation (after Anderson *et al.*, 2015).
(a) 2D horizontal FD grid with uniform nodal spacing; i = columns and j = rows[9]. The cells are block-centred; the heavy dark line represents the problem domain. Inactive cells (those outside the boundary of the problem domain) are shaded.
(b) 2D horizontal FD grid with notation for the group of five nodes comprising the FD computational module (star) centred around node (i,j).
(c) 3D notation where Δz represents the vertical distance between nodes and k is the vertical index. The group of blocks at the right is shown in 2D space (the two blocks perpendicular to the page along the y-axis are not shown). The group of seven nodes including node (i,j,k) comprise the FD computational module in three dimensions.

2.5.2 Finite element methods

In the FE method, the continuous flow field is discretised into a number of elements, which are used for interpolation of the field parameters such as the head and hydraulic conductivity (Figure 2-5). The locations of elements are designated using spatial coordinates (x, y, z) in a two dimensional (2D) or 3D mesh. The mesh consists of a triangulated irregular network (TIN) representing the modelled space. The basic idea is to transform the governing equations into integral form and evaluate flow rate by carrying out piecewise integration over small-volume elements in space and time. The FE method starts by mathematically defining the potential surface over any small region of interest and then evaluates the gradient in any given direction by evaluating directives in that direction (Thangarajan, 2007).

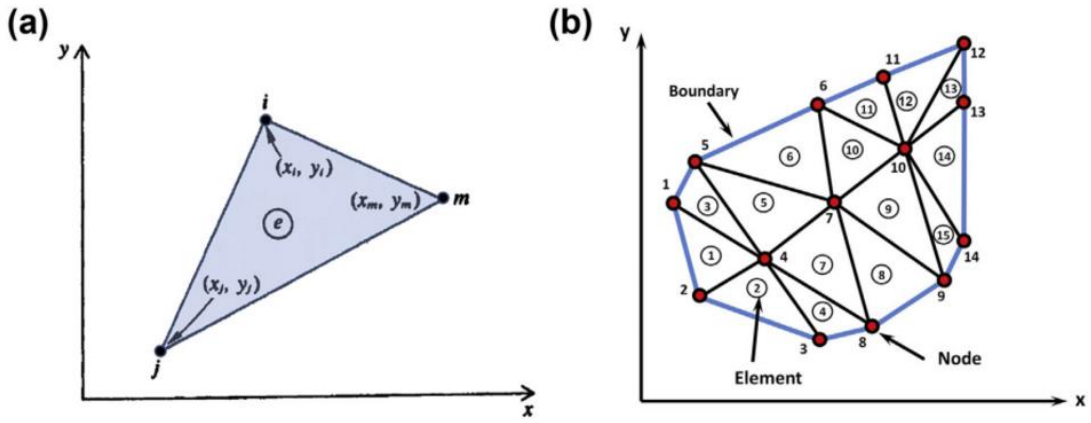

Figure 2-5. Two-dimensional (2D) horizontal finite-element mesh with triangular elements and notation (after Anderson *et al.*, 2015).
(a) A representative triangular element with nodes $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{m}$, labelled in counter clockwise order, with spatial coordinates ($\boldsymbol{x}$, $\boldsymbol{y}$).
(b) Triangular elements, with element numbers inside circles, are defined by numbered nodes. The elements are fitted to the boundary of the problem domain.

The FE equations are generated by introducing a trial solution of head within the element by interpolation functions, usually called basis functions, that relate head at the nodes to head within the element. Linear interpolation function is commonly used but more complex functions like the inverse distance weighted (IDW) and Kriging may be necessary. In addition, many of the more sophisticated interpolation techniques include options that could be used to refine the solution.

2.6 Modelling method and code selection

There are other additional mathematical groundwater modelling methods to the ones discussed above. These methods are either analytical (too many to list), numerical (e.g. the control volume finite difference; CVFD), or hybrid (e.g. the analytical element method; AEM). Because of their high calculations demand, all numerical and analytical element models require the use of digital computers. So, various computer codes have been written to implement these methods.

Different groundwater modelling codes implement modelling methods differently, and many of them allow the use of various numerical iteration techniques (solvers) to solve groundwater flow problems. For example, the United States Geological Survey (USGS) modular FD code (MODFLOW) allows the use of a number of

numerical solvers to execute calculations, including the Strongly Implicit Procedure (SIP), Conjugate-Gradient (PCG) and the Direct Solver (DE4), to name some. In addition, many public-domain, shareware and proprietary software have been developed to provide convenient graphical user interfaces (GUI) for various codes (e.g. Visual MODFLOW Flex by Waterloo Hydrogeologic for MODFLOW and GMS by Aquaveo for MODFLOW, FEMWATER, MODAEM and other codes). GUIs enable convenient pre-processing of data for input in the appropriate format to the selected modelling code, running the code seamlessly with easy viewing and manipulating of the modelling results (post-processing). Alternatively, general mathematical software packages such as MATLAB and COMSOL can be used to solve the general groundwater flow PDE (Eq. 2-8) (Anderson *et al.*, 2015).

The complexity of the LMC groundwater system renders analytical and analytical element solutions unsuitable to simulate it. So, the choice is realistically limited to numerical models that are based on FD, FE and CVFD methods, such as MODFLOW, FEFLOW and MODFLOW-USG, respectively. FE and CVFD methods are more difficult to use than FD methods and there are no clear gains from using them to model the LMC groundwater system.

On face value, the MODFLOW code seems to be the most plausible choice for modelling the LMC groundwater system but there are numerous other modelling codes that could also be used. Anderson *et al.* (2015) list four important criteria for groundwater modelling code selection: (1) code verification (2) water budget computation ability and accuracy, (3) proven track record, and (4) availability and capabilities of GUIs. In addition, the possibility of using automated calibration tools is an important criterion that should be considered during mathematical modelling code selection. The following sections briefly assess how MODFLOW measures against each of the above criteria.

2.6.1 Code verification

Numerical modelling codes are verified by comparing their results to the results of analytical solutions and other numerical codes. The principle objective of code verification is to ensure it has been appropriately programmed.

Since the original release of MODFLOW (McDonald & Harbaugh, 1984), it has been the most widely used code to solve groundwater flow problems (Anderson *et al.*, 2015). The first release was followed by MODFLOW 2000 (Harbaugh *et al.*, 2000) and MODFLOW 2005 (Harbaugh, 2005). The code's modular design was particularly advantageous as proven by the code's wide use and the large number of enhancement and additions to the original code (McDonald & Harbaugh, 2003). Recently, the ability to use an unstructured grid has been added to the software (Panday *et al.*, 2013) and was implemented in many GUIs such as Aquaveo's GMS and Groundwater Vistas by Environmental Simulations, Inc. (ESI).

Because of its effectiveness and wide use, MODFLOW has become an industry standard. It is globally used to verify nearly all analytical and numerical models, old and new. Thereby, MODFLOW itself has become the most verified code in the groundwater modelling arena. This gives confidence in its ability to simulate the LMC groundwater system efficiently.

2.6.2 Water budget calculations

Water budget calculations are an essential component in hydrogeological studies. Accordingly, they have become standard features of most codes. Comparison of field observations-based water budget calculations that normally form part of conceptual models (e.g. Table 5-3) to numerical model computations provide a means to assess the accuracy of the numerical solution. Numerical models water budgets itemise flows across boundaries, to and from sources and sinks, user specified zones, and in transient simulations to and from storage.

It is important to notice that the governing equation for groundwater flow is derived from combining Darcy's law with conservation of mass (Section 2.3). Hence,

numerical solutions of the governing equation should conserve mass, which the FE method has reportedly failed to achieve locally (Berger & Howington, 2002). Anderson *et al.* (2015) argue that this is due to flawed methodology in early FE solutions and not inherent to the FE method. They indicate that modern FE codes include procedures that compute numerically accurate water budgets. Difference in model calculated inputs and outputs represent a water budget balance error. According to Konikow (1978), that is ideally less than 0.1%, but it would still be acceptable up to around 0.5%. High water budget balance error may be due to conceptualisation deficiencies, unreasonably high solution converged closure criteria, or low maximum number of iterations allowed. It could also reflect errors in input and/or model design, or it could be an artefact of how the code simulates head-dependent boundaries.

Both the FD method and all versions of the MODFLOW code are well-known for their ability to maintain highly accurate water budgets. Consequently, no serious water budget errors are expected from the use of MODFLOW to model groundwater in the LMC.

2.6.3 Proven track record

MODFLOW is the most widely used groundwater code in the world and the standard for litigation purposes in many countries, including and led by the United States (Anderson *et al.*, 2015). It has been applied to numerous and diverse field problems and is the focus of a wide range of international conferences. This history of successful use and testing provide an unmatched track record to any modelling code. The code's extensive use over more than 30 years in academic and professional settings enabled errors to be discovered and corrected, new modules (packages and processes) to be developed and a variety of GUIs to become available. A main advantage of MODFLOW over other codes is that it is supported by the USGS who put it in the public domain free of charge to users. This encouraged users and GUI developers alike to use it and contribute to its development, particularly because MODFLOW is an open source code.

With such a track record, there is no risk arising from utilisation of MODFLOW code in modelling the LMC groundwater system.

2.6.4 Availability and capabilities of GUIs

Most modelling codes require data input in specific tabular text format and output results in the form of numerical tables, both of which are not particularly user friendly. Therefore, an interface between the modeller and the code is needed to facilitate data preparation, code runs and manipulation of results. User interfaces are software designed to serve as intermediary between the modeller and the code, most often providing the modeller with a visual (graphical) working environment. They facilitate model design, data input and enable easy visualisation, inspection and analysis of outputs. GUIs help designing grids and meshes as applicable to the code and boundaries. GUIs also assist in the exchange of data between various computer applications, especially with mapping, GIS and database packages. GUIs enable modellers to focus on the actual model build rather than data entry and visualisation of input and model results. Anderson *et al.* (2015) see that due to the complexity of most numerical modelling projects, a GUI is an indispensable tool for groundwater modelling.

MODFLOW code does not include an embedded GUI but a range of GUIs have been developed for it. The USGS has put ModelMuse MODFLOW GUI in the public domain (Winston, 2009) and ModelMate for parameter estimation using UCODE with MODFLOW (Banta, 2011). Freeware MODFLOW GUIs like Processing MODFLOW for Windows (PMWIN) and commercial packages like Groundwater Vistas, Visual MODFLOW-flex and the Groundwater Modelling System (GMS) are also available.

Often, MODFLOW GUIs handle several versions of the code (e.g. MODFLOW-SURFACT, MODHMS, MODFLOW-USG) and many enable conjunct or consequential use of automated parameter estimation codes (e.g. PEST) and other useful software such as particle tracking codes (e.g. MODPATH) and solute transport codes (e.g. PATH3D, MT3DMS, SEAWAT).

The availability of GUIs and other compatible modelling packages for parameter estimation and transport modelling makes MODFLOW a good choice for modelling the LMC groundwater system.

2.7 Modelling software package selection

As noted above, MODFLOW GUIs are by no means in short supply. However, prudent selection of the modelling software package will definitely maximise benefits and minimise risk and cost in terms of money, time, effort and quality of output. Criteria similar to those used for code selection apply to GUI selection. Most popular packages tick all the selection criteria but the United States Department of Defense (DoD) Groundwater Modeling System (GMS) stands out as a capable, user-friendly, flexible, intuitive GUI.

GMS was initially developed at Brigham Young University (BYU), then commercialised through EMS-I, a BYU commercial enterprise. In 2007, GMS software development was moved to a private enterprise, Aquaveo, LLC. Due to US government support, GMS is available at no cost to the US DoD, the Environmental Protection Agency (EPA), the Department of Energy (DoE), the Nuclear Regulatory Commission (NRC), the National Aeronautics and Space Administration (NASA) and onsite contractors to these agencies. The software is available through Aquaveo commercially to professionals and at a discounted rate for academic users.

GMS provides an integrated graphical system for modelling the subsurface environment, including stratigraphy, flow, contaminant transport and fate. The software possesses remarkable 2D and 3D geostatistical capabilities (e.g. Kriging, IDW and Natural Neighbour) and seamlessly utilises and integrates ESRI's ArcGIS technology.

In GMS, stratigraphy can be modelled deterministically using horizons and solids or stochastically through T-PROGS. Groundwater flow modelling can be undertaken using a variety of methods including analytical element (MODAEM), FD

(MODFLOW), and FE (FEMWATER). GMS supports all MODFLOW versions (88, 96, 2000, 2005, NWT, LGR[10] and USG[11]) and most existing packages (Table 2-1). Both steady-state and transient modelling are possible with the GUI supporting real date/time format and interpolation of transient data. Modelling of contaminant transport is possible through MODPATH, MT3DMS, PHT3D, SEAWAT, RT3D, and SEAM3D. Stochastic groundwater modelling is possible through Monte Carlo, Latin Hypercube and Gaussian Field. GMS has built in ZONEBDGT code and supports the Model-Independent Parameter Estimation and Uncertainty Analysis (PEST) software by Doherty (2015), which could be used for model calibration and sensitivity analysis. The software also supports Parallel PEST, Monte Carlo simulations, calibration targets, plots and charts.

GMS has excellent visualisation capabilities which enable easy interaction with models in 2D and 3D. The software is capable of producing high quality contour maps, cross-sections, fence diagrams and block diagrams for stratigraphy and hydrology.

The most important feature in GMS is perhaps its conceptual modelling approach, which the software pioneered to then be followed by other major groundwater modelling packages. The conceptual approach enables constructing a high-level representation of the model using familiar GIS objects such as points, arcs and polygons and easy updating of the model as may be required.

Consequently, GMS appears to be very well suited for modelling the LMC groundwater system using MODFLOW codes and other supported software needed to achieve this research's objectives.

[10] LGR: local grid refinement.
[11] USG: unstructured grid.

Table 2-1. GMS supported MODFLOW packages (modules).

Package	Description
BAS6	Basic Package
BCF6	Block Cantered Flow Package
CHD1	Time Variant Specified Head Package
DE4	Direct Solver
DRN1	Drain Package
DRT1	Drain Return Package
EVT1	Evapotranspiration Package
ETS1	Evapotranspiration Segments Package
GAGE	Gage Package
GHB1	General Head Boundary Package
GMG	Geometric Multi-Grid
HFB1	Horizontal Flow Barrier Package
HUF	Hydrogeologic Unit Flow Package
LAK3	Lake Package
LPF	Layer Property Flow Package
MNW1	Multi-Node Well 1 Package
MNW2	Multi-Node Well 2 Package
NWT	Newton Solver
OUT1	Output Control
PCG2	Preconditioned Conjugate Gradient Method
PCGN	Preconditioned Conjugate Gradient Solver with Improved Nonlinear Control
RCH1	Recharge Package
RIV1	River Package
SAMG	Algebraic MultiGrid for Systems Solver
SFR2	Streamflow-Routing Package
SIP	Strongly Implicit Procedure
SOR	Slice-Successive Overrelaxation Method
SUB	Subsidence Package
STR1	Stream-Routing Package
WEL1	Well Package
UPW	Upstream Weighting Flow Package
UZF1	Unsaturated-Zone Flow Package

2.8 Modelling approach

Groundwater modelling is an exigent undertaking, which needs to be carefully managed to produce a satisfactory output. Every groundwater system is unique and, therefore, the modelling approach must be tailored to the specific circumstances of the project. Principally, objectives of modelling vary, data availability differs, time, technical and financial resources are not the same for all models, and subjective choices are inevitable. In addition, groundwater modelling is an active field of research and developments are driven by the need for better

hydrogeological process expressions, newly encountered management issues and expanding mathematical and computing capabilities. Consequently, attempts to prescribe an orchestrated and repeatable hydrogeological modelling protocol proved to be unviable. Instead, modelling and model auditing guidelines have been developed (e.g. Barnett *et al.*, 2012; PDP, 2002; Wels *et al.*, 2012). Such guidelines attempt to represent what is considered good practice in groundwater modelling, based on historical and current literature and the experience of practitioners involved in the guidelines development. Development of guidelines must be reviewed and updated continually to keep up with the changing questions being asked of modelling, mathematical and software developments and transformations in modelling approaches.

It is noticed that successful groundwater models are developed through a phased approach that incorporates what could be considered common typical steps. Comparable modelling workflows have been proposed by various investigators (e.g. Anderson *et al.*, 2015; Barnett *et al.*, 2012; Kumar, 2004; PDP, 2002; Wels *et al.*, 2012; Younger, 2007). Figure 2-6 presents a flow chart illustrating the typical sequence of steps involved in groundwater modelling.

The modelling approach in this thesis generally follows the Younger (2007) workflow presented in Figure 2-6 and the Australian groundwater modelling guidelines (Barnett *et al.*, 2012). Following such best-practice methodology facilitates the modelling process and results in a robust modelling outcome.

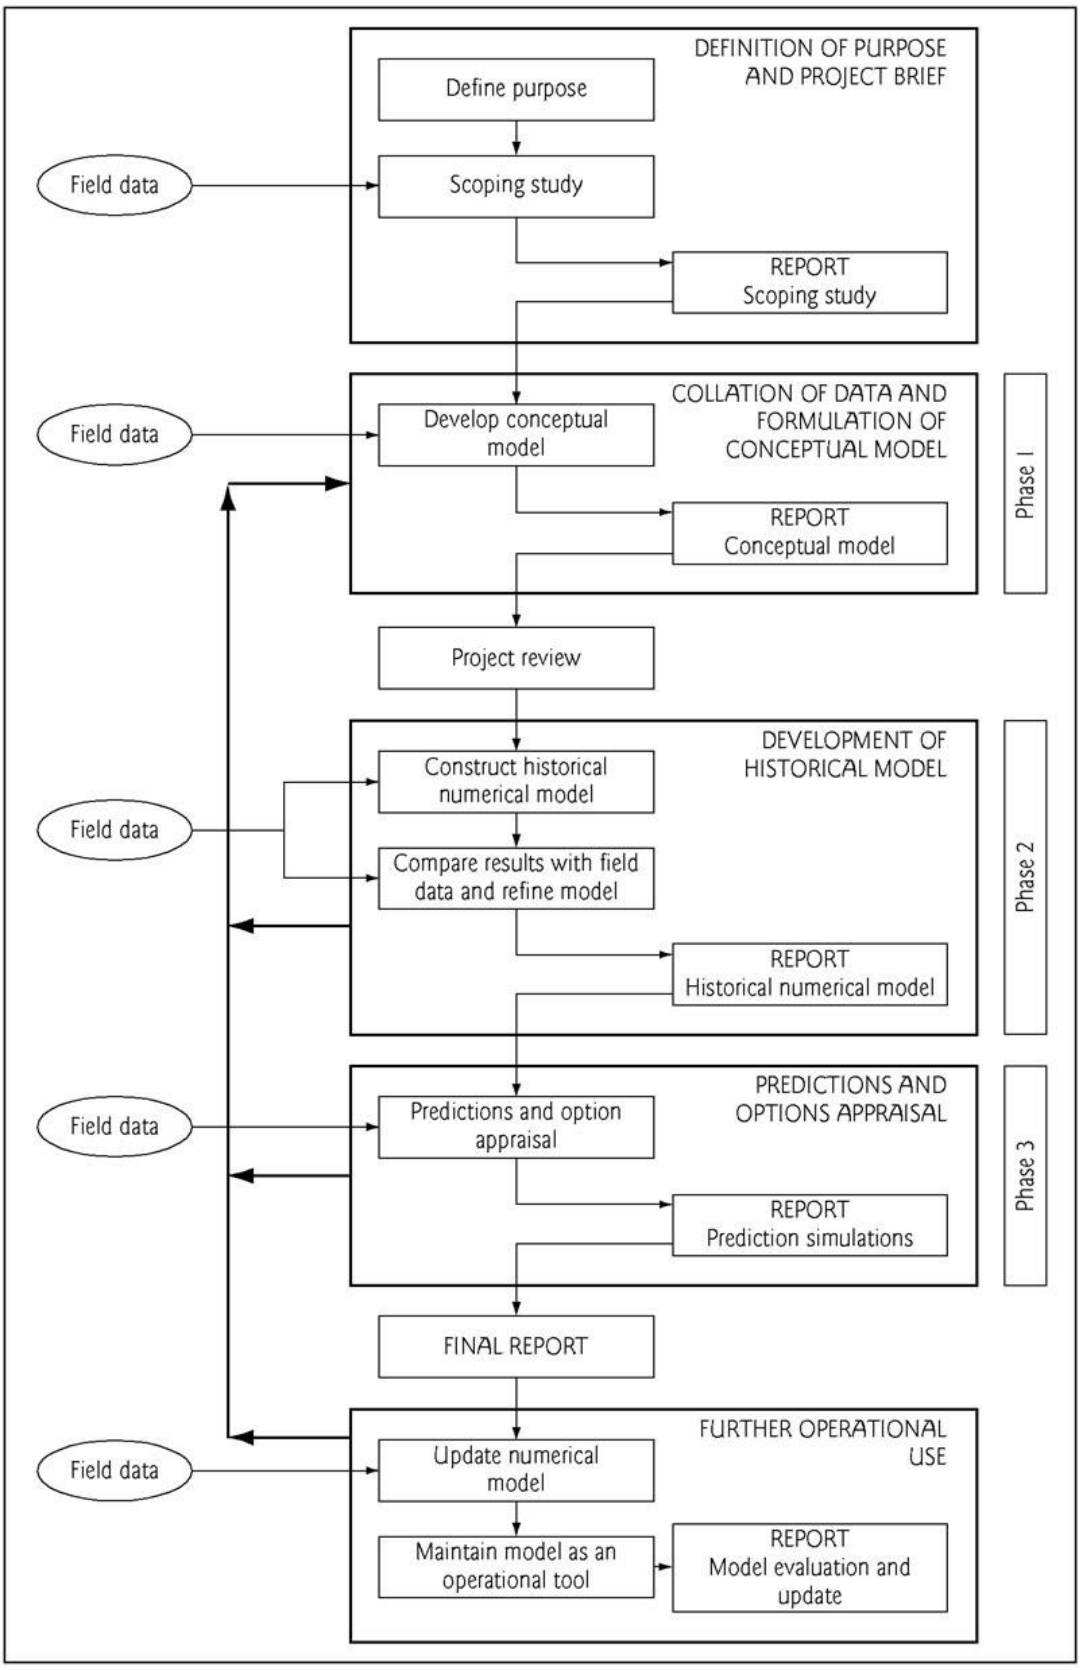

Figure 2-6. Flow chart illustrating the typical sequence of steps involved in groundwater modelling (after Younger, 2007).

2.9 Calibration

Model calibration implicates adjusting independent variables (parameters and fluxes) within sensible ranges to achieve the best fit between measured and model calculated groundwater heads and water balance components like flow exchanges (gains and losses) with surface water features. Hence, it is a form of inverse analysis or modelling. It is an iterative trial and error process of systematic parameter adjustment until a set calibration target is achieved. It can be undertaken manually but this a tedious and subjective process. Because of their higher level of complexity, it is more difficult to manually calibrate transient models than steady-state models. Manual calibration is greatly beneficial as it enables the modeller to examine the conceptual model and have a sense of the sensitivity of the model output to changes in input parameters. Commonly, manual calibration is followed by automated inverse parameter estimation, which reduces subjectivity inherent in the manual data matching process and enables quantification of parameter sensitivity.

Groundwater models are subject to non-uniqueness, where more than one set of parameters can produce the same model results. For example, recharge and hydraulic conductivity are highly correlated in groundwater flow models and, therefore, various combinations of these two parameters can produce the same result. Therefore, a calibrated model does not imply that it is the only feasible representation of the modelled system. While there is always just one reality, there are infinite possibilities to represent it.

Remarkably, not all models need to be calibrated to be useful. The Australian groundwater modelling guidelines recognises that in some cases model calibration is not necessary, such as when using a model to test a conceptual model (Barnett *et al.*, 2012). Furthermore, in some cases numerical modelling itself may not be needed. Younger (2007) notes that conceptual models do not necessarily have to be followed by mathematical modelling as they '*are largely ends in themselves.*'

2.9.1 Targets

When calibrating a model using automated parameter estimation (inverse modelling), a target measurement Objective Function (Φ) defining an acceptable level of model to measurement misfit is defined as

$$\Phi = \Sigma(w_i\, r_i)^2 \qquad 2\text{-}27$$

where $r_i = (h_{calculated} - h_{observed})$ and w_i is a weighting factor assigned to each observation. Inverse modelling aims at minimising the Objective Function ($h_{calculated}$ and $h_{observed}$ are the calculated and observed heads, respectively). Flux can also be incorporated in equation 2-27.

The weight assigned to each of the observations points is a function of the standard deviation. It is calculated as

$$W = \frac{1}{\sigma^2 * GW} \qquad 2\text{-}28$$

where W is the weight of the observation point, σ is the standard deviation for the observation and GW is the observation points group weight. The observation point weight is multiplied by the residual for the observation in the objective function. Obviously, the smaller the standard deviation of an observation point the greater it will influence the objective function.

Often, the standard deviation is not known, but an error interval and level of confidence can be assigned to an observation that is desired to be used in model calibration, e.g. a head measurement with ±1 m acceptable/expected error and 95% level of confidence in the measurement within that range. These data can be converted into standard deviation and used in inverse modelling. In practical terms, specifying an interval (or standard deviation) and confidence is an indication of how much error is believed to be associated with the observed value.

GMS GUI allows entry of observation data with standard deviation or confidence interval. It also facilitates model calibration by graphical presentation of calibration

targets on a map of the model in the form shown in Figure 2-7. The error bar is colour coded to indicate the goodness of the match between observed and calculated values. Green means the calculated value falls within the calibration target, yellow means that the calculated value is outside the target range but the error is no more than 200%, and red denotes that the error is greater than 200%.

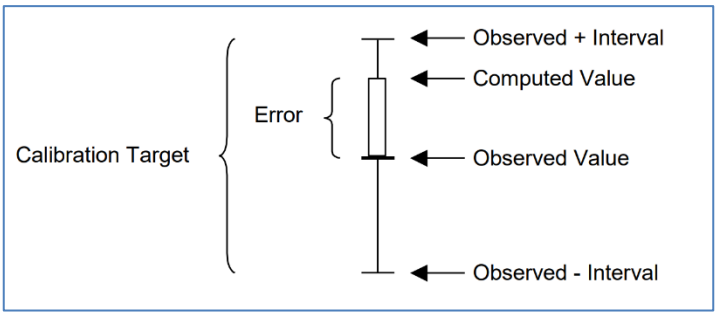

Figure 2-7. Model calibration target.

2.9.2 Calibration goodness circumstantial and statistical assessment

Assessing the quality of calibration of a groundwater flow model involves comparing the calibrated model results to anecdotes (e.g. unquantified field observations, piezometric maps and analytical flow estimates) and statistical evaluation of the fitness of computed values to actual measurements. Important and commonly used statistical metrics include:

1. Calculated-observed data agreement

A scatter plot of calculated against observed values provides a useful visual means to assess the goodness of the model calibration. Clearly, the closer the points to the 1:1 ratio, the better the match between observed and calculated data. Data points plotting above the 1:1 line indicates model overestimation (positive residual) and data points falling under the line represent negative residual. Therefore, it is useful to draw lines to represent certain disagreement intervals in such graphs, e.g. ±10 m as implemented in Section 8.10 (Figure 8-12).

2. R-squared (R^2)

R-squared (R^2), the coefficient of determination, is a statistical measure of how close the data are to the fitted regression line. It represents the percentage of the

response variable variation that is explained by a linear model. The lowest possible value (0%) indicates that the model explains none of the variability of the response data around its mean and the maximum possible value (100%) indicates that the model explains all the variability of the response data around its mean. The higher the R^2 the better the model fits the data.

3. Mean residual

The calibration residual (R_i) is defined as the difference between the calculated results (X_{cal}) and the observed results (X_{obs}) at data points $i \rightarrow n$. The mean residual ($\bar{R}$) is a measure of the average residual value:

$$\bar{R} = \frac{1}{n}\sum_{i=1}^{n} R_i \qquad 2\text{-}29$$

There may be cases where over and under calculated values will negate each other, producing mean residual ($\bar{R}$) value close to zero, which can lead to false interpretation of the model calibration. Therefore, $\bar{R}$ should never be used by itself as a measure of fitness between simulated results and observed data.

4. Mean absolute residual

The mean absolute residual ($|\bar{R}|$) is a measure of the average magnitude of the residuals and, therefore, provides a better indication of calibration than $\bar{R}$.

$$\overline{|R|} = \frac{1}{n}\sum_{i=1}^{n} |R_i| \qquad 2\text{-}30$$

5. Root mean squared residual

The root mean squared residual (RMS) is calculated by taking the average of the square of the errors for the observations and then taking its square root. It tends to give more weight to cases where a few extreme error values exist.

$$RMS = \sqrt{\frac{1}{n}\sum_{i=1}^{n} R_i^2} \qquad 2\text{-}31$$

Chapter 3 Geology and soil

3.1 Introduction

Stratigraphy and geological structure determine the extent and configuration of hydrogeological systems and lithology determines their hydraulic properties. Stratigraphy describes the geometrical and relative age of various strata in layered sedimentary and volcanic systems. Structural geology describes the 3D distribution of geological units with respect to their deformational histories, including folding and faulting. Lithology is a description of the physical makeup of the sediments or rocks, including mineral composition, grain-size, sorting and packing, all of which control the ability of geological material to store and bear water. On the other hand, the potential for groundwater reserves to be replenished is chiefly determined by land cover (soil and vegetation) and physiographical setting (landforms). Often, physiography is confused and/or used interchangeably with geomorphology. In this thesis, physiography is used to denote the classification of landforms and geomorphology is used to indicate studying the processes involved in the development of landforms.

3.2 Geological and conceptual uncertainty

Given the degree to which geology determines the nature of groundwater systems, sound geological conceptualisation and modelling is considered prerequisite to reliable conceptual and mathematical hydrogeological models. Refsgaarda *et al.* (2012) elucidate that groundwater models are affected by two main sources of uncertainty relating to geology: (a) geological structures, and (b) hydraulic parameter values within these structures. Hydraulic parameters are commonly heterogeneous and anisotropic. Heterogeneity occurs at various scales. Heterogeneity and anisotropy can be accounted for in groundwater models, but they are often neglected in the assessments of model uncertainty.

There are a variety of methods for assessing hydrogeological modelling uncertainty related to geological uncertainty. Such methods include multiple modelling, Monte Carlo analysis, regression analysis and moment equation approach (Refsgaarda *et al.*, 2012). Ye *et al.* (2010) explored how alternative conceptual models can be evaluated to give insight into conceptual uncertainty. They found out that overall model uncertainty is greatly more susceptible to conceptual uncertainty rather than parametric uncertainty. Furthermore, they found that uncertainty in geological interpretations had a more significant effect on model uncertainty than changes in recharge estimates. These findings are important because groundwater system conceptualisation and modelling depend on geological conceptualisation and, hence, they automatically inherit geological uncertainty. Understanding the regional geological setting and geological history forms the basis for geological conceptualisation.

3.3 Data sources

The geological understanding presented in this thesis is developed from synthesising information from accessible literature and databases. Accessed databases include digital maps and models. Limited field reconnaissance has been undertaken to validate information from literature and to achieve better understanding of the study area's geological setting.

3.3.1 Ground elevation data

Land surface elevation data was obtained from the digital elevation model (DEM) created by the Otago University School of Surveying through interpolating Land Information New Zealand (LINZ) topographical vector data (Columbus *et al.*, 2011). The DEM known as NZSoSDEM v1.0 covers the whole of New Zealand at a spatial resolution of 15 m. It consists of a series of 30 maps that correspond exactly with the extent of the LINZ Topo250 topographical map series. DEM files are available from koordinates.com under Creative Commons Public License (CCPL). The study area spans four DEM maps, namely:

1. Map 08 – New Plymouth
2. Map 10 – Napier

3. Map 14 – Palmerston North
4. Map 15 – Dannevirke.

The above-listed four NZSoSDEM maps have been combined to form a single DEM for the study area using ArcGIS 10.4 for Desktop (ArcGIS)[12]. These maps are supposed to fit together seamlessly. However, upon inspection, it was found that they contain some topological imperfections (slivers and overlaps). ArcGIS was used to check and correct topology problems in the amalgamated DEM. Attempts to extend the DEM coverage offshore using New Zealand 250 m Bathymetry Grid (2008) obtained from koordinates.com under CCPL proved unsatisfactory as the resolutions of the two datasets are quite different. The final DEM for the LMC and vicinity is presented in Figure 3-1. It is used in physiographical and geomorphological analyses, to estimate the elevation of wells that have not been surveyed, to obtain outcrop elevations for lithostratigraphical modelling and to determine the elevations of hydrogeological model layers.

3.3.2 Geological maps

Published 1:250 000 geological map sheets and associated reports are amongst the most important sources of information for this study. The quarter million geological map (QMAP) sheets and associated reports by GNS Science provide information about surface geology and some structural data, which can be interpreted through cross-sections for example to obtain an approximate knowledge of the subsurface geology. The study area is covered by four QMAP sheets, namely:

1. Taranaki – QMAP Sheet 7 (Townsend *et al.*, 2008)
2. Hawke's Bay – QMAP Sheet 8 (Lee *et al.*, 2011)
3. Wellington – QMAP Sheet 10 (Begg & Johnston, 2000)
4. Wairarapa – QMAP Sheet 11 (Lee & Begg, 2000).

[12] © Copyright 2015 Environmental Systems Research Institute, Inc. (ESRI).

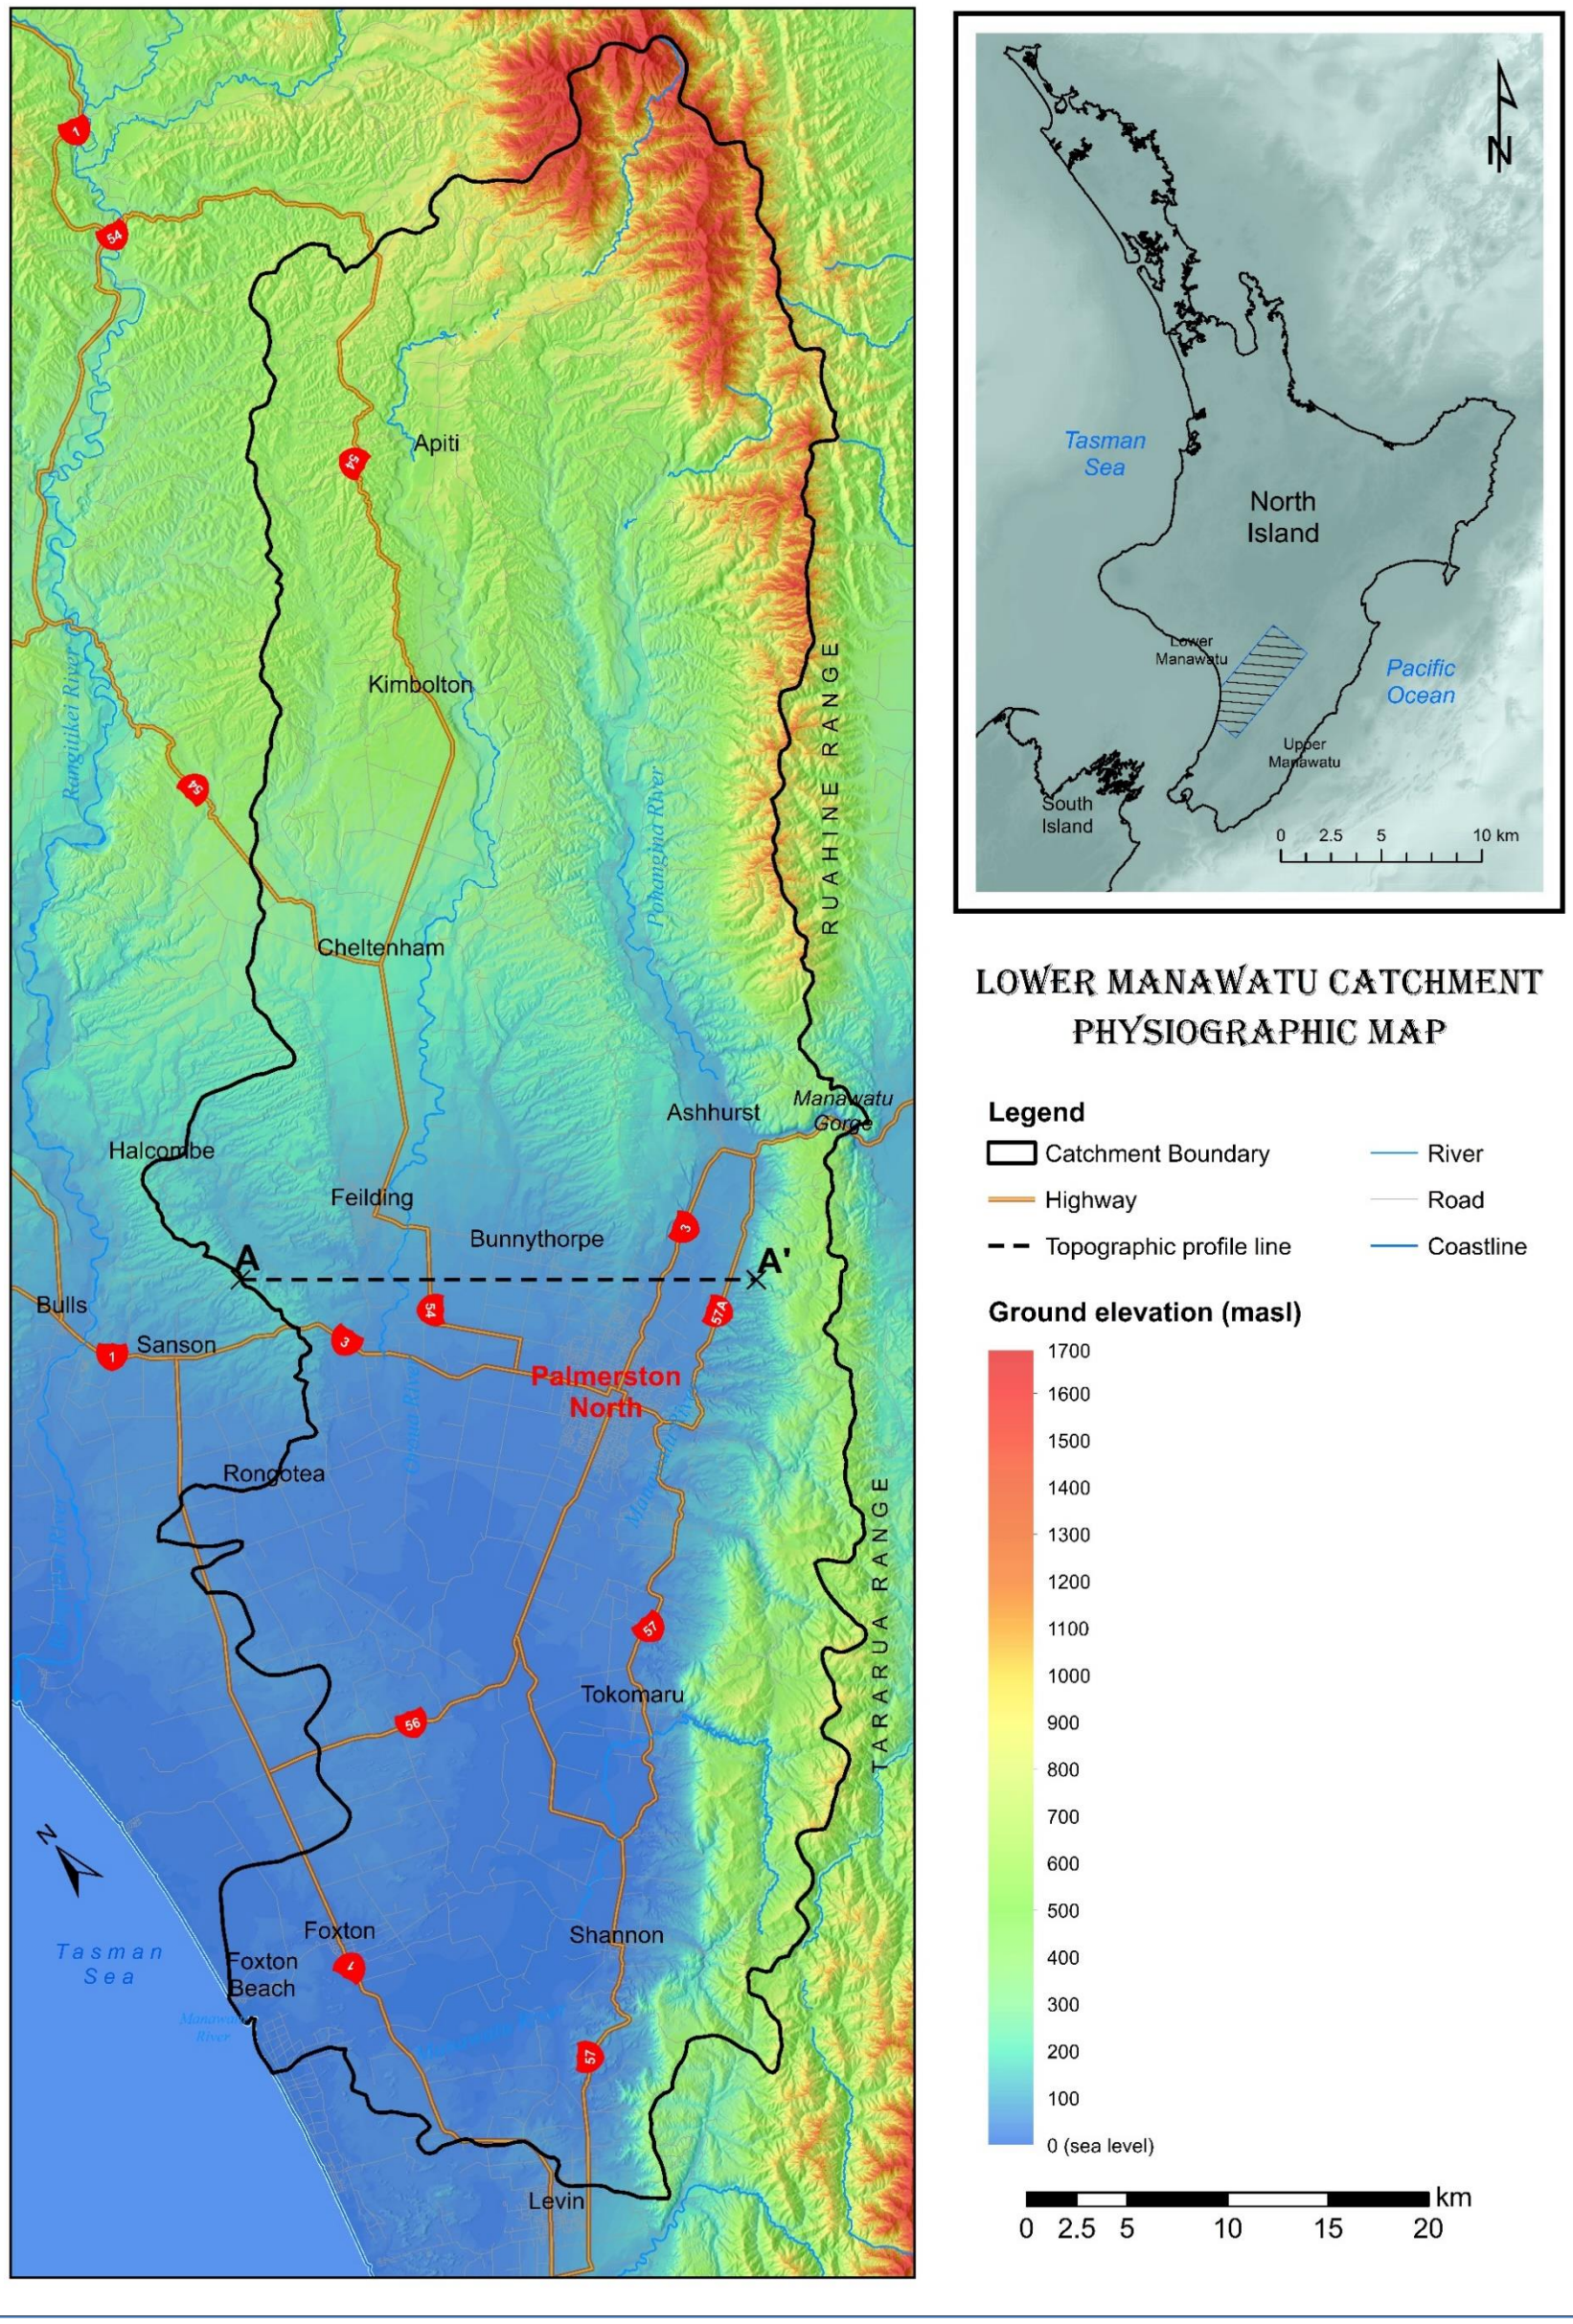

Figure 3-1. Physiographical map sourced from digital elevation model data.
For topographical profile, see Figure 3-10.

The fact that the study area extends over four QMAP sheets complicates geological assessments. The maps were drawn at different times, using different data sets, coding and symbology systems. Therefore, geological units and boundaries at the edges of the above-listed four geological map sheets do not always match. In many cases, it was noticed that disagreement of geological unit codes is due to better data/standards being used in newer map sheets.

Heron (2014) amalgamated all QMAP geological map sheets in a single ArcGIS project. This map is free of topological errors. Nonetheless, it has not unified geological unit codes across the different QMAP sheets. To enable catchment-scale geological analysis, the amalgamated geological map has been checked and a single stratigraphical unit coding system has been developed (Table 3-1). The final geological map for the study area is presented in Figure 3-2. Colours and symbols used in this report may differ slightly from those used in published GNS Science QMAP sheets.

Geological chronology in this thesis is based on New Zealand Geological Timescale v. 2015/1 (Figure 3-3).

3.3.3 Horizons Regional Council groundwater database

Zarour *et al.* (2011) portrays the groundwater monitoring programme in the Manawatu-Wanganui (Horizons) region, in which the LMC is situated. Horizons Regional Council has a corresponding database to store and manage groundwater information. Most of the hydrological and hydrogeological data used for this study had been obtained from Horizons groundwater database, including data on well locations, drillers' well logs, groundwater levels and groundwater quality parameters.

Table 3-1. Geological units and map codes.

Rock group	Age[13]	Map code[14]	General characteristics
Holocene	OIS1	Q1dm	Windblown loose sand in active unvegetated or sparsely vegetated dune fields and deflation zones.
		Q1ds	Windblown inactive undifferentiated dunes and associated facies.
		Q1f	Poorly sorted, poorly consolidated alluvial, colluvial and scree fan deposits consisting of angular to sub-rounded boulders, cobbles, pebbles, gravel, sand and clay.
		Q1l	Earthflow hill slope deposits containing poorly sorted clasts up to boulder size in a clay matrix.
		Q1a	Poorly consolidated (loose), well sorted alluvial gravel, sand, silt and clay with local peat in modern floodplains and low terraces.
Late Quaternary	OIS2	Q2f	Poorly sorted, weakly consolidated alluvial and colluvial steep fan gravel deposits consisting gravel, sand, silt and clay.
		Q2a	Poorly to moderately sorted alluvial gravel with minor sand and silt underlying terraces.
	OIS3	Q3f	Alluvial and colluvial fan deposits consisting of poorly sorted, weakly consolidated gravel, sand, silt and clay.
		Q3a	Moderately weathered, poorly to moderately sorted alluvial gravel with minor sand and silt underlying loess-covered, commonly eroded aggradational surfaces.
	OIS4	Q4f	Moderately weathered alluvial and colluvial fan deposits underlying eroded terraces consisting of poorly to moderately sorted, weakly consolidated gravel, sand, silt and clay.
		Q4a	Weathered, poorly to moderately sorted alluvial gravel with sand and silt.
	OIS5	Q5b	Rapanui, Hauriri and Inaha terrace beach and shallow marine coverbed deposits consisting of conglomerate, shellbeds, dune sands and peat commonly underlying loess and fan deposits.
	OIS5-2	lQf	Undifferentiated moderately weathered poorly sorted alluvial gravel, sand, silt and clay.
		lQl	Landslide deposits ranging from coherent shattered masses of rock to unsorted fragments in a fine-grained matrix.
		lQa	Undifferentiated moderately weathered poorly sorted loess-covered alluvial gravel deposits.
Middle Quaternary	OIS6	Q6f	Very weathered alluvial and colluvial steep fan deposits consisting of poorly sorted, weakly consolidated gravel, sand, silt and clay.
	OIS7	Q6a	Very weathered, poorly to moderately sorted gravel with minor sand and silt underlying eroded terraces.
	OIS8	Q8a	Weathered, poorly to moderately sorted alluvial gravel underlying loess-covered, commonly eroded aggradational surfaces.
	OIS9	Q9b	Braemore and Brunswick terrace coverbeds comprising beach and shallow marine conglomerate, shellbeds, dune sands, mud and peat.
	OIS10	Q10a	Weathered, poorly to moderately sorted gravel with minor sand and silt underlying eroded terraces loess covered.

[13] OIS: Oxygen Isotope Stage (also known as Marine Isotope Stage; MIS) or geological time unit name.
[14] Symbols require QMAP Text true type font.

Rock group	Age[13]	Map code[14]	General characteristics
Early Quaternary	Castlecliffian	Q11b	Gravel, sand and mud.
		eQa	Weathered, poorly sorted loess-covered alluvial and fan gravel, pumiceous sand and lacustrine silt deposits.
		eQp	Lacustrine and shoreline fluvial sediments.
		e-mQs	Sandstone, siltstone, bioclastic limestone and conglomerate, including OIS 15-9 marine terrace deposits. Sandstone, siltstone, bioclastic limestone and conglomerate, including OIS 15-9 marine terrace deposits. Early Pleistocene - Middle Pleistocene sedimentary rocks.
		eQk	Coarse pumice grit, tephra, sand, silt, shellbeds and conglomerate. Sandstone, siltstone, bioclastic limestone, conglomerate and pumiceous sand. Early Pleistocene sedimentary rocks.
		eQo	Sandstone, siltstone, conglomerate and shell beds. Early Pleistocene sedimentary rocks.
Neogene	Pliocene-Pleistocene	ℙep	Limestone.
		ℙea	Massive, poorly bedded deeper water mudstone and sandy mudstone with minor alternating limestone, siltstone, sandstone and shallow water conglomerate.
		ℙi	Sandstone, concretionary sandstone, mudstone, limestone and conglomerate.
		ℙm	Pumiceous and non-pumiceous sandstone, mudstone, conglomerate, carbonaceous siltstone, lignite and shell beds.
		ℙio	Alternating limestone, sandstone and siltstone.
		ℙik	Alternating siltstone, sandstone and limestone.
		ℙim	Weakly bedded, cross-bedded, bioturbated sandstone, siltstone and conglomerate.
		ℙp	Thin pebbly shell beds and massive, well sorted sandstone in the west, and massive silty mudstone, concretionary sandstone; limestone and conglomerate in the east.
		ℙuo	Conglomeratic limestone and sandstone.
		ℙu	Muddy, very fine sandstone, concretionary sandstone and sandy mudstone.
		ℙit	Massive mudstone interbedded with well sorted, fine to medium, micaceous sandstone.
Mesozoic (Eastern Provence Basement)	Triassic-Early Cretaceous	Ktw	Well-bedded alternating sandstone and mudstone.
		Ktp	Alternating sandstone and mudstone, massive mudstone and concretionary mudstone. Well bedded sandstone and mudstone.
		Kep	Sandstone blocks and packets of thin-bedded sandstone and mudstone in a sheared mudstone matrix. Basement (Eastern Province) melange.
		Tev	Small to large blocks of basalt within melange zones. Basement (Eastern Province) igneous rocks.
		Te	Sandstone and mudstone in a sheared argillite matrix with broken formation and melange.
		Jtk	Massive sandstone to alternating sandstone and argillite.
		Ttt	Alternating sandstone and mudstone, poorly bedded sandstone with minor coloured mudstone, conglomerate, basalt and chert.

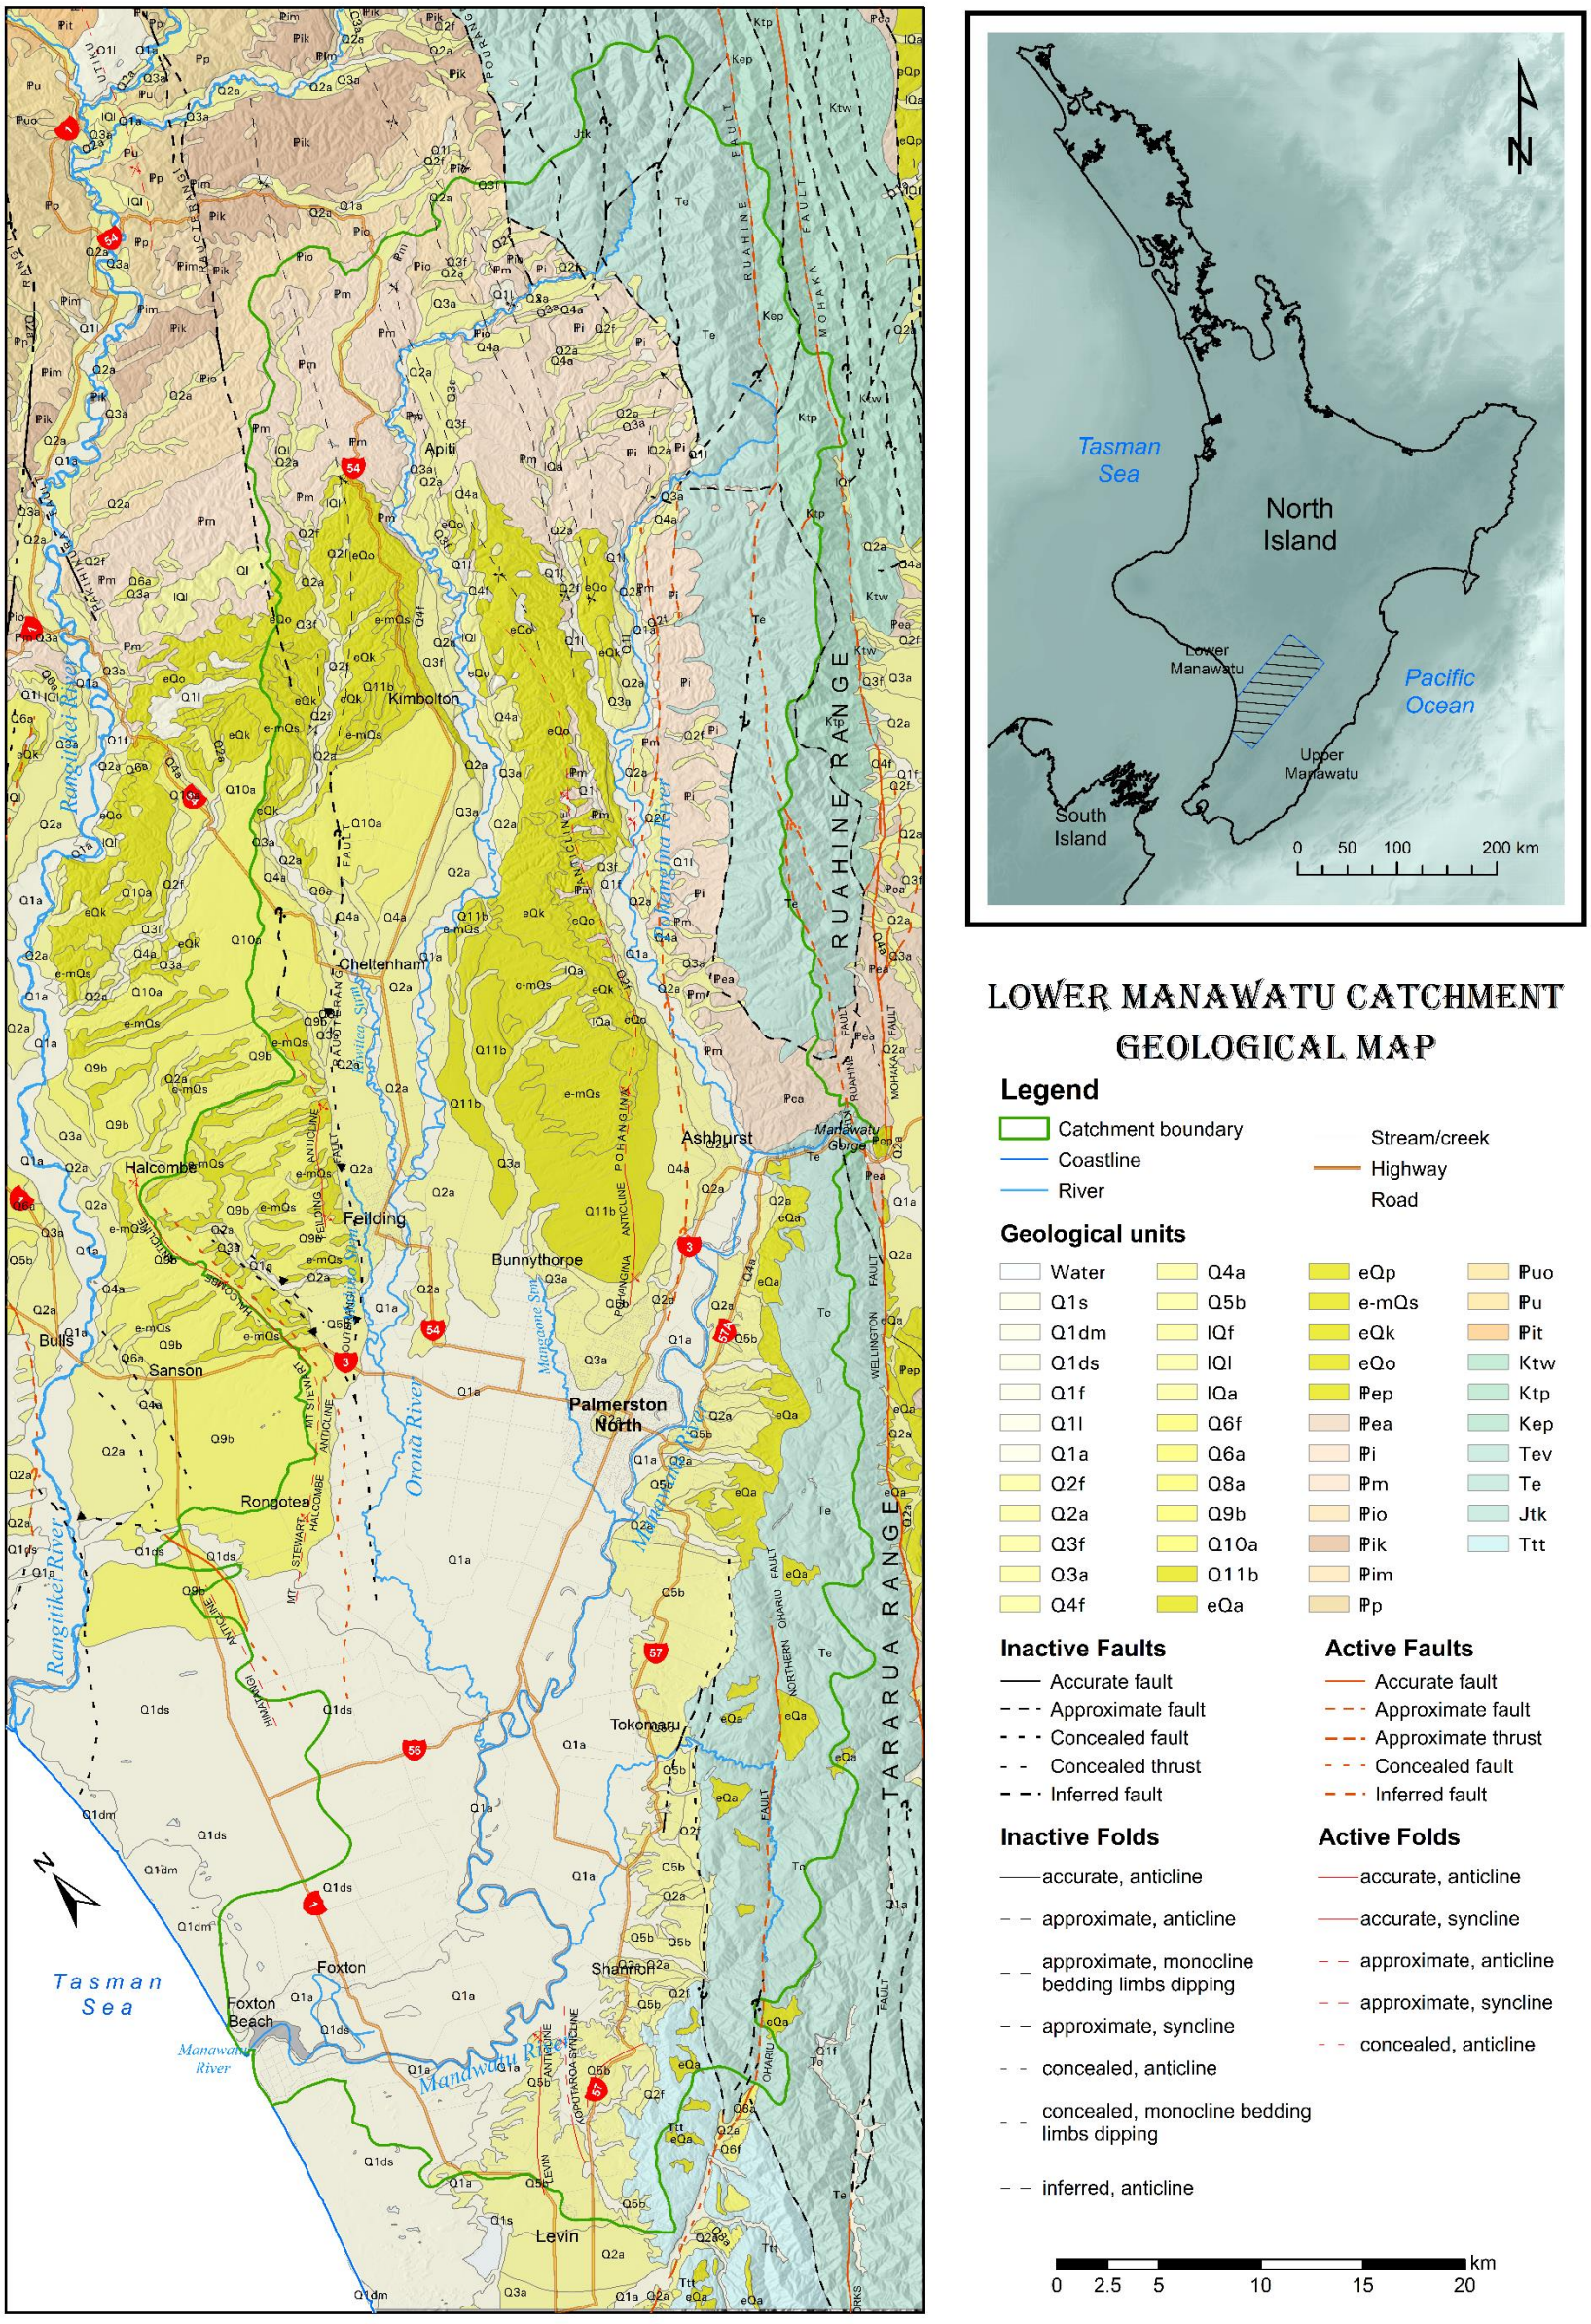

Figure 3-2. Geological map based on digital QMAP data (Heron, 2014).

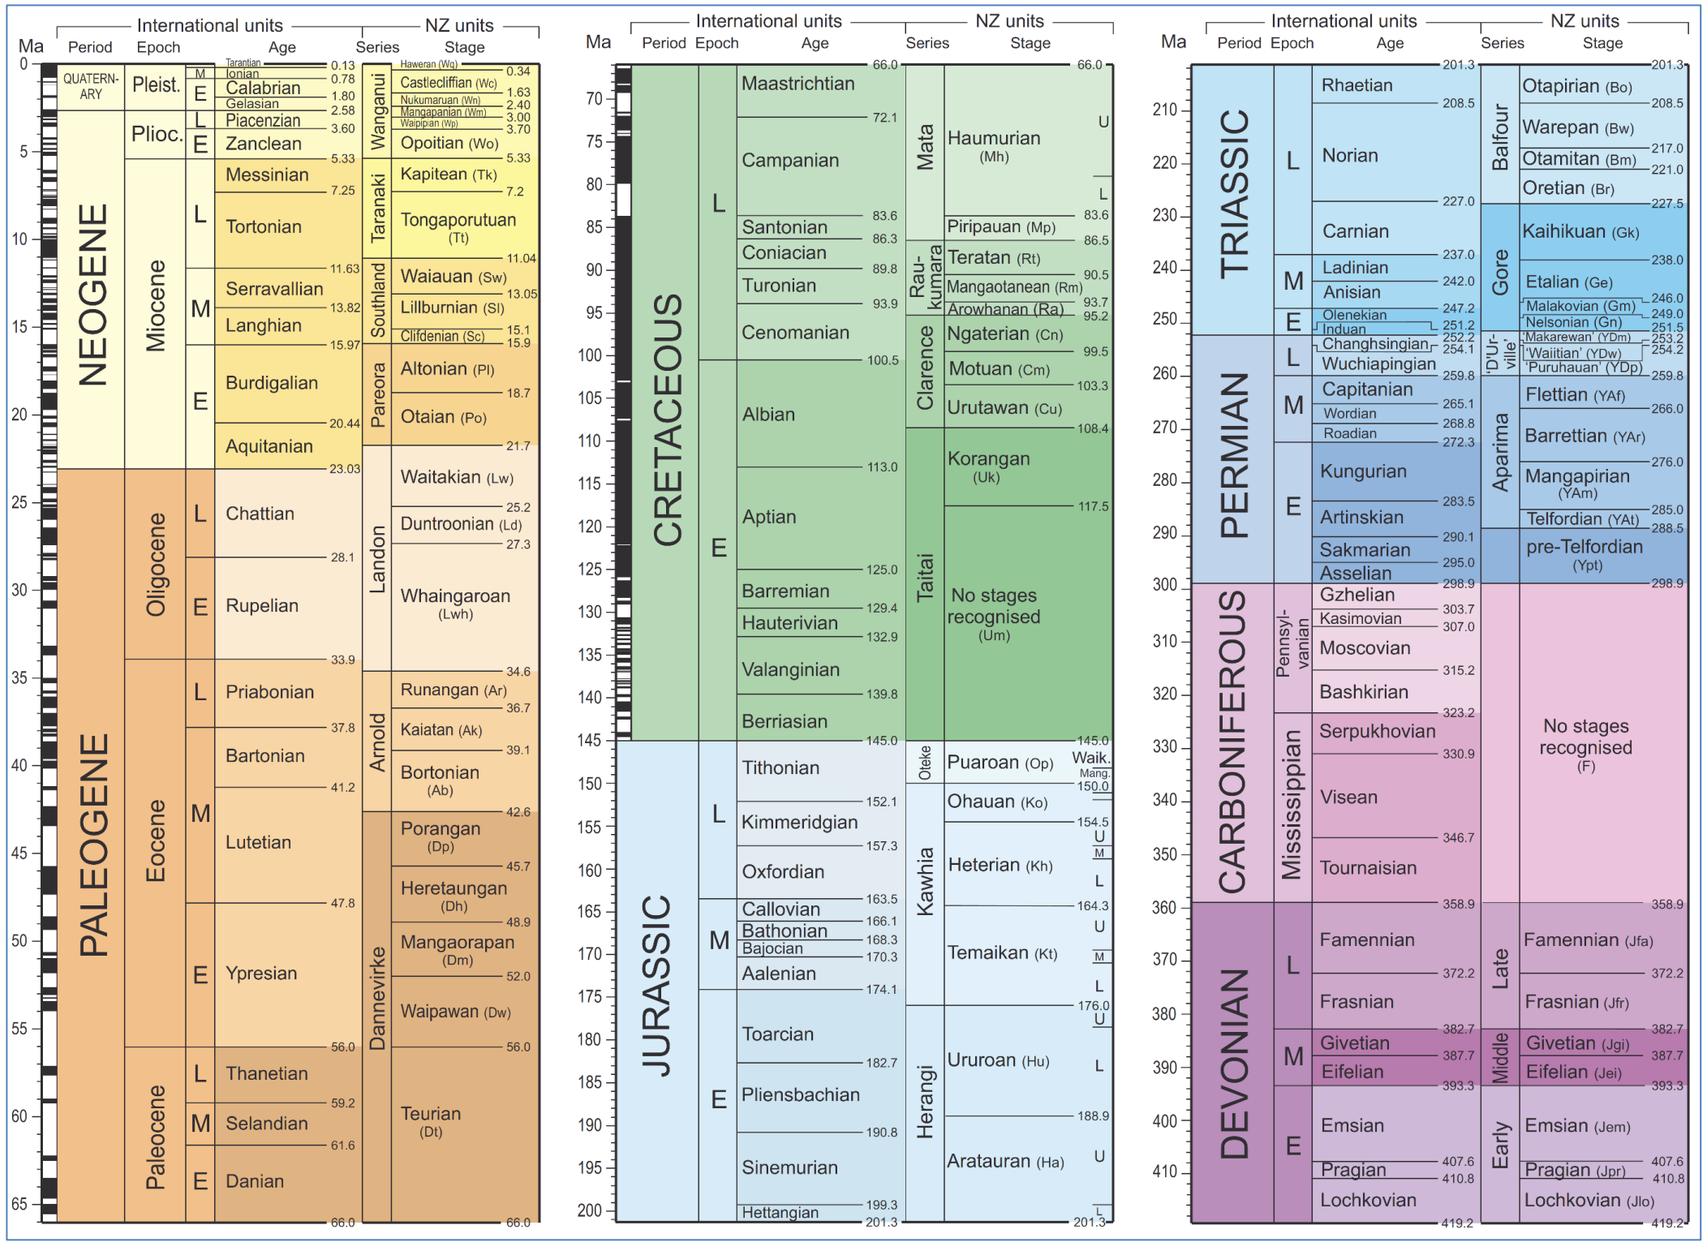

Figure 3-3. New Zealand and international geological timescales (Extracted from GNS Sicence, 2015).

3.3.4 Soil data

Soil data for this research were obtained from the New Zealand Soils Portal[15], which provides access to information on New Zealand's soils held by Landcare Research. Landcare is undertaking national-scale soil mapping, the S-map. The S-map is the most recent digital soil spatial information system for New Zealand. It is intended to provide consistent and comprehensive national soil data layers to support applications at local, and regional to national-scales. However, there is not yet S-map coverage for the study area. Therefore, this research uses Landcare's Fundamental Soil Layers (FSLs) data, which predate and are being replaced by the S-map.

The FSLs contain spatial information for 16 key soil attributes. Each attribute is measurable (i.e. given a numerical value rather than being assigned to a descriptive class or category) and is recorded in appropriate units of measure. Because FSLs attributes have measurable values, the FSLs are particularly useful in computer modelling and GIS analyses. The 16 key soil attributes generally fall into three groups: (1) soil fertility/toxicity, (2) soil physical properties particularly those related to soil moisture, and (3) topography and climate. Parameters include slope, potential rooting depth, topsoil gravel content, proportion of rock outcrop, pH, salinity, cation exchange capacity, total carbon, phosphorus retention, flood interval, soil temperature, total profile available water, profile readily available water, drainage, and macro-pores (shallow and deep). The attributes are described in detail in the New Zealand Soil Classification (NZSC) by Hewitt (2010). LMC soils are described in Section 3.13 of this thesis.

3.4 Regional geological setting

The LMC is situated in the Pliocene-Pleistocene (Plio-Pleistocene) Wanganui Basin in the Lower North Island of New Zealand, approximately 200 km northwest of the Hikurangi Trough at the southern end of the Tonga-Kermadec subduction zone, which forms the boundary between the Australian and Pacific crustal plates (Figure

[15] https://lris.scinfo.org.nz

3-4). The two plates move relative to one another on the earth's surface, and are converging at a rate of about 40-50 mm/y (Begg & Johnston, 2000). As a result, the thicker, lighter continental Australian Plate overrides the thinner, denser oceanic Pacific Plate in the New Zealand region (Figure 3-5). Much of the strain associated with the collision is transferred to the leading edge of the Australian Plate, the landmass of the North Island. This strain produces the crumpled physiography of the sea floor to the east of the North Island, in the landmass itself, and in the sea floor to the west of the North Island (Begg *et al.*, 2005) (Figure 3-6).

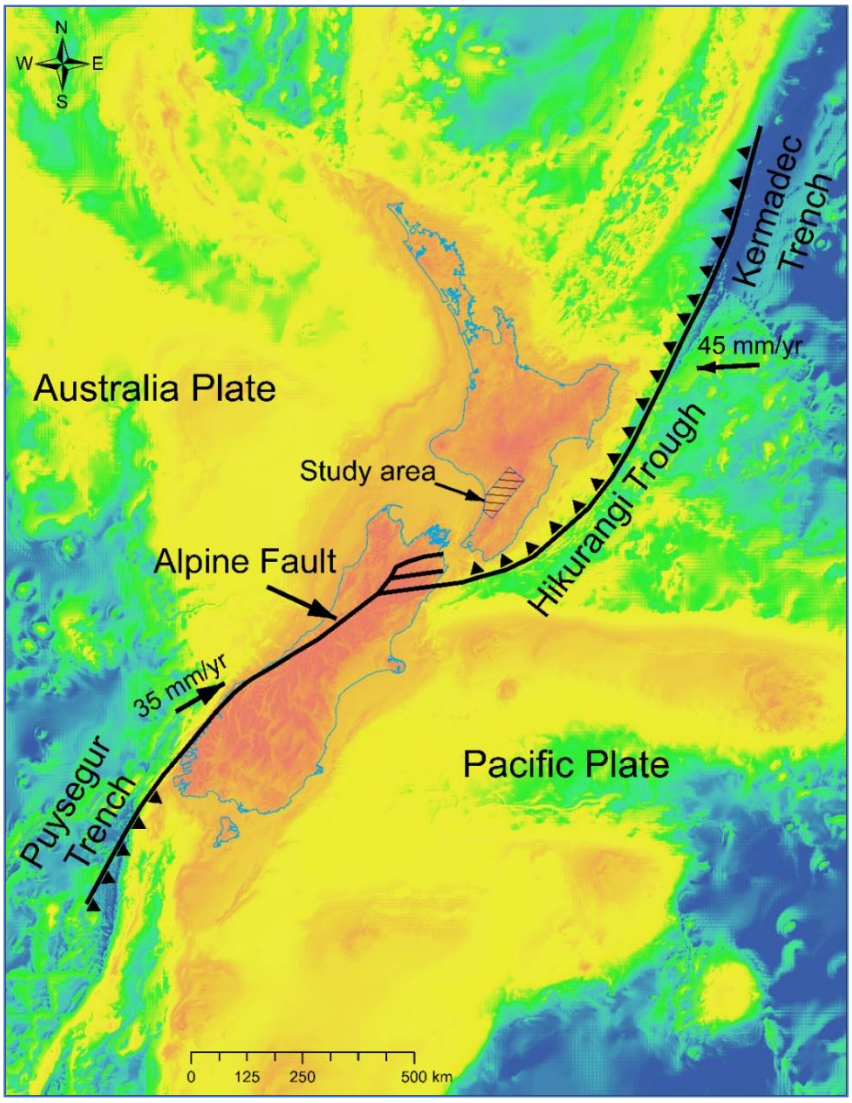

Figure 3-4. Tectonic setting of New Zealand.

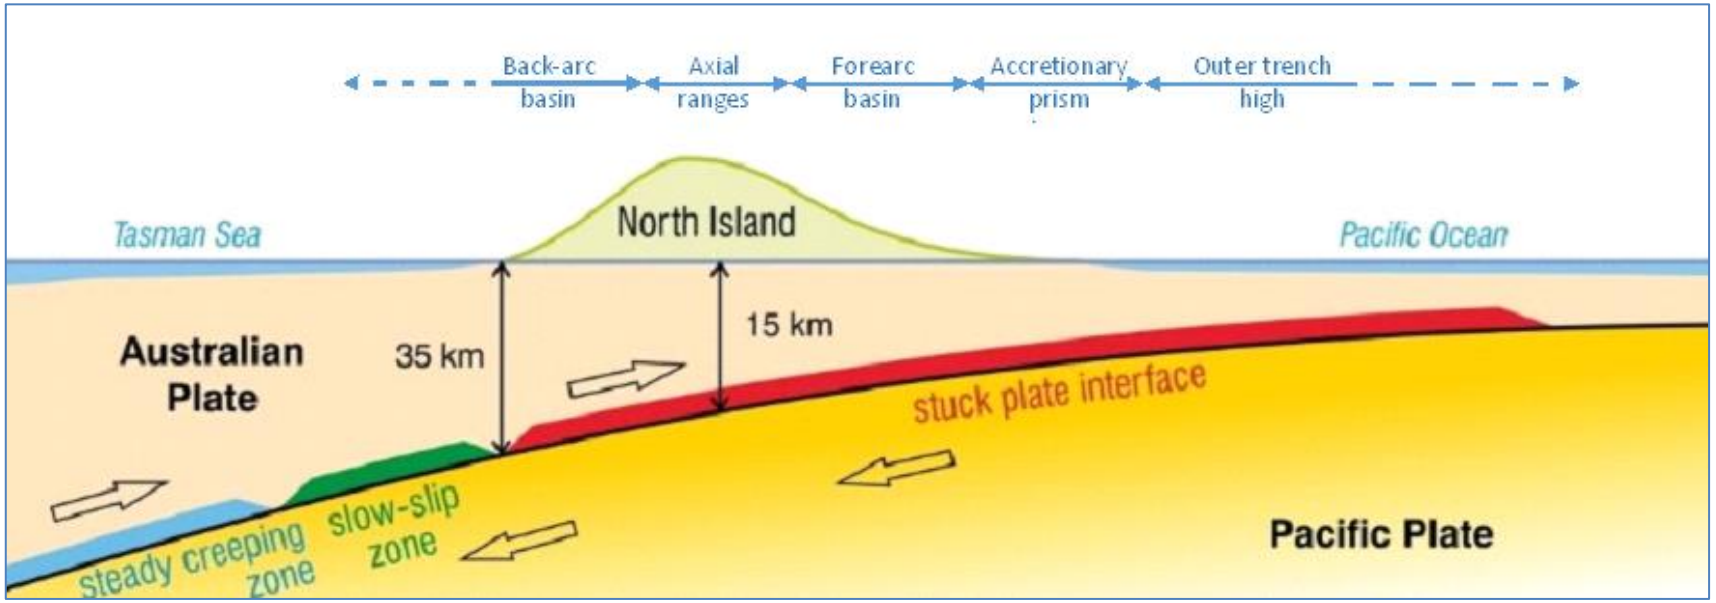

Figure 3-5. Schematic of plate interface beneath southern North Island viewed from Cook Strait (modified after Little, 2013).

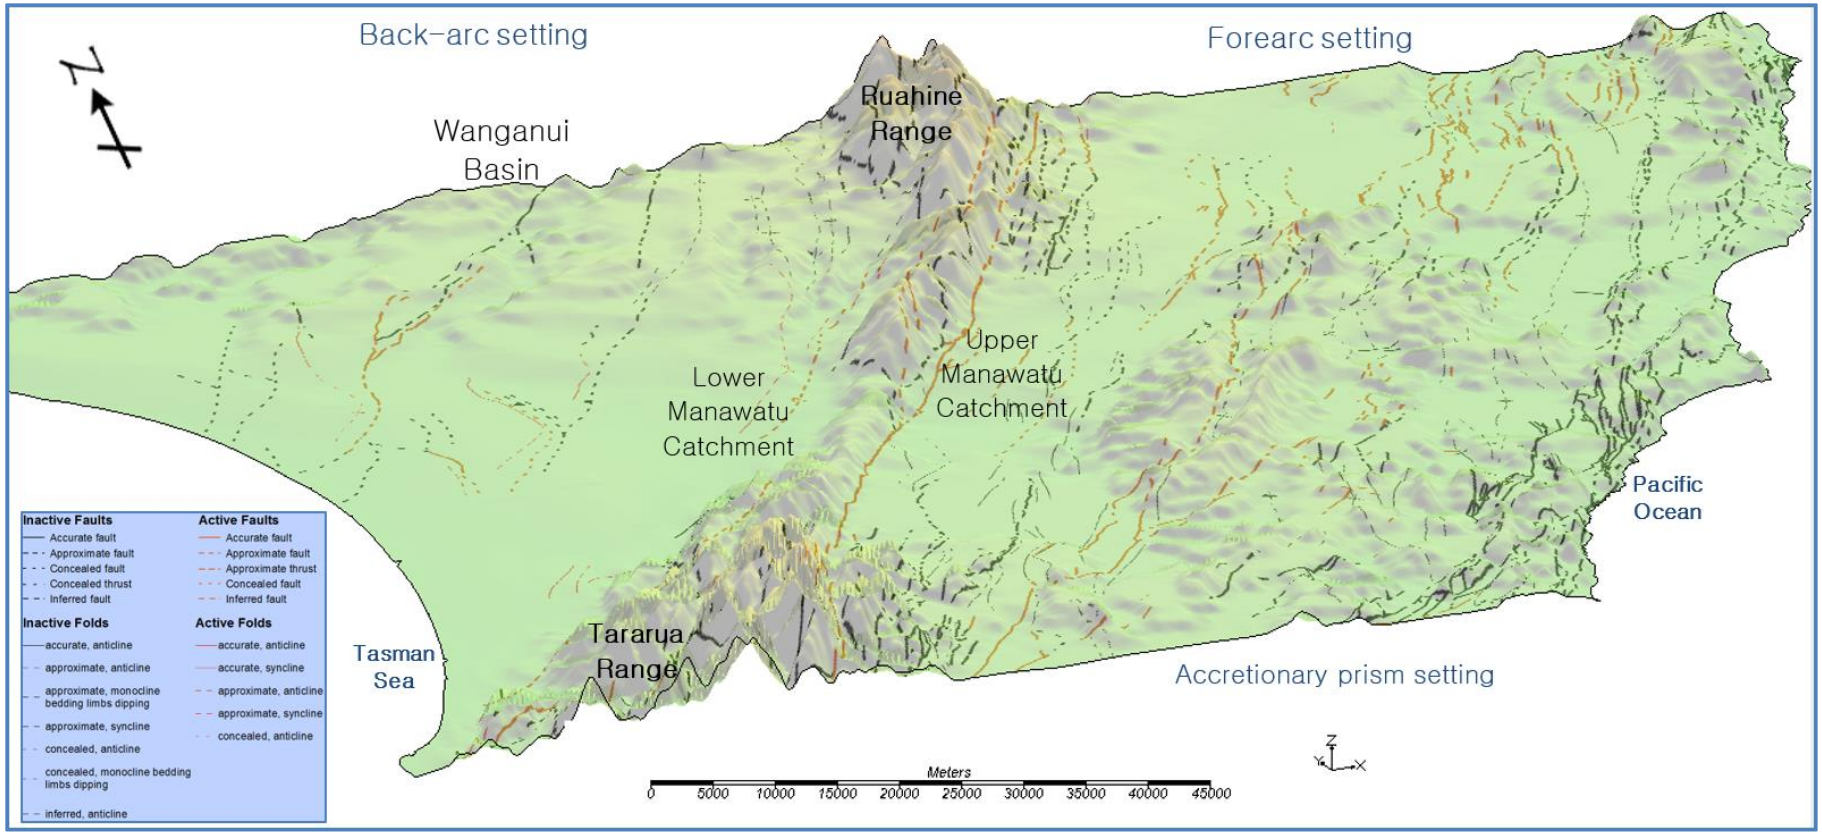

Figure 3-6. Three-dimensional impression of the southern North Island showing effect of tectonic setting on structural geological setting.

The top of the overridden Pacific Plate dips ever deeper northwest of the Hikurangi Trough, and can be found at depth beneath the landscape of the North Island (c. 30 km beneath the Manawatu River mouth). Strain associated with the plate boundary is transferred up through the overriding Australian Plate to the ground surface in the form of active folds and faults (Figure 3-2 through Figure 3-7). This deformation, both the broad regional strain and the more local deformation associated with faults and folds significantly influences the hydrogeological environment (Begg *et al.*, 2005).

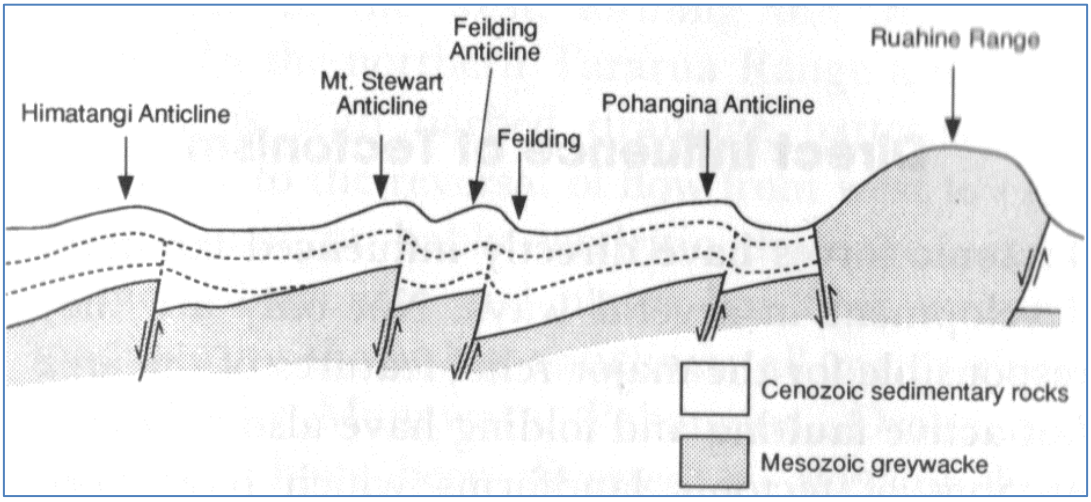

Figure 3-7. Sketch section between Tangimoana and the Ruahine Ranges showing the relationship between structure and relief (after Heerdegen & Shepherd, 1992).

Active reverse faults in the study area are bounded by asymmetrical growing folds (Figure 3-7). Progressive growth of these folds elevated their crests above major rivers valley floors, isolating them from alluvial deposition. Consequently, areas underlying active folds in the Wanganui Basin form interfluves, channelling the major river catchments down the fault zones and synclinal axes between anticlines. Cool climate aggradational alluvial gravels were deposited in these loci, forming highly productive aquifer zones (Begg *et al.*, 2005).

3.5 Structure

The Wanganui Basin is affected by regional and local-scale tectonic deformation relating to its back-arc setting (Pillans, 1994) within the transition zone between the convergent Tonga-Kermadec subduction system to the northeast and the Alpine Fault continent-continent transform to the southeast (Figure 3-4) atop the subducting Pacific Plate (Brackley, 1999) (Figure 3-5). Regional tectonics is responsible for deep marine deposition in the Wanganui Basin during the early Pliocene and its subsequent uplift in the Late Pliocene and Pleistocene. The cause of this regional uplift (and eversion of the Wanganui Basin) is uncertain, but may be associated with processes at the southern end of the Taupo Volcanic Zone, and/or with deeper crustal processes associated with the subduction interface (Begg *et al.*, 2005).

In addition to regional-scale tectonic uplift, smaller scale shallower deformation has profoundly influenced young deposits in the Wanganui Basin. These structures are probably rooted near the subduction interface. They form a series of northeast to north-northeast striking faults through the area (Figure 3-8). Seismic reflection work indicates that these reverse faults associated with folding (Anderton, 1981; Lamarche *et al.*, 2005; Melhuish *et al.*, 1996). Some of these faults dip westward and some dip eastward. Where they fail to penetrate to the land surface, their presence may be signalled by asymmetrical folds (Figure 3-7). These folds generally have sigmoidal axes, gently dipping northwest flanks and more steeply dipping eastern flanks (Figure 3-7). Displacement on these faults was initiated at least as long ago as earliest Pleistocene. The major ones are still active. They have greatly influenced Middle and Late Quaternary deposition in the area. Not only has fold development progressively lifted their crests above the influence of fluvial action, but they also have confined river channels to the synclines.

The following sections provide an account of the main structural features in the study area based mainly on the description of Begg *et al.* (2005).

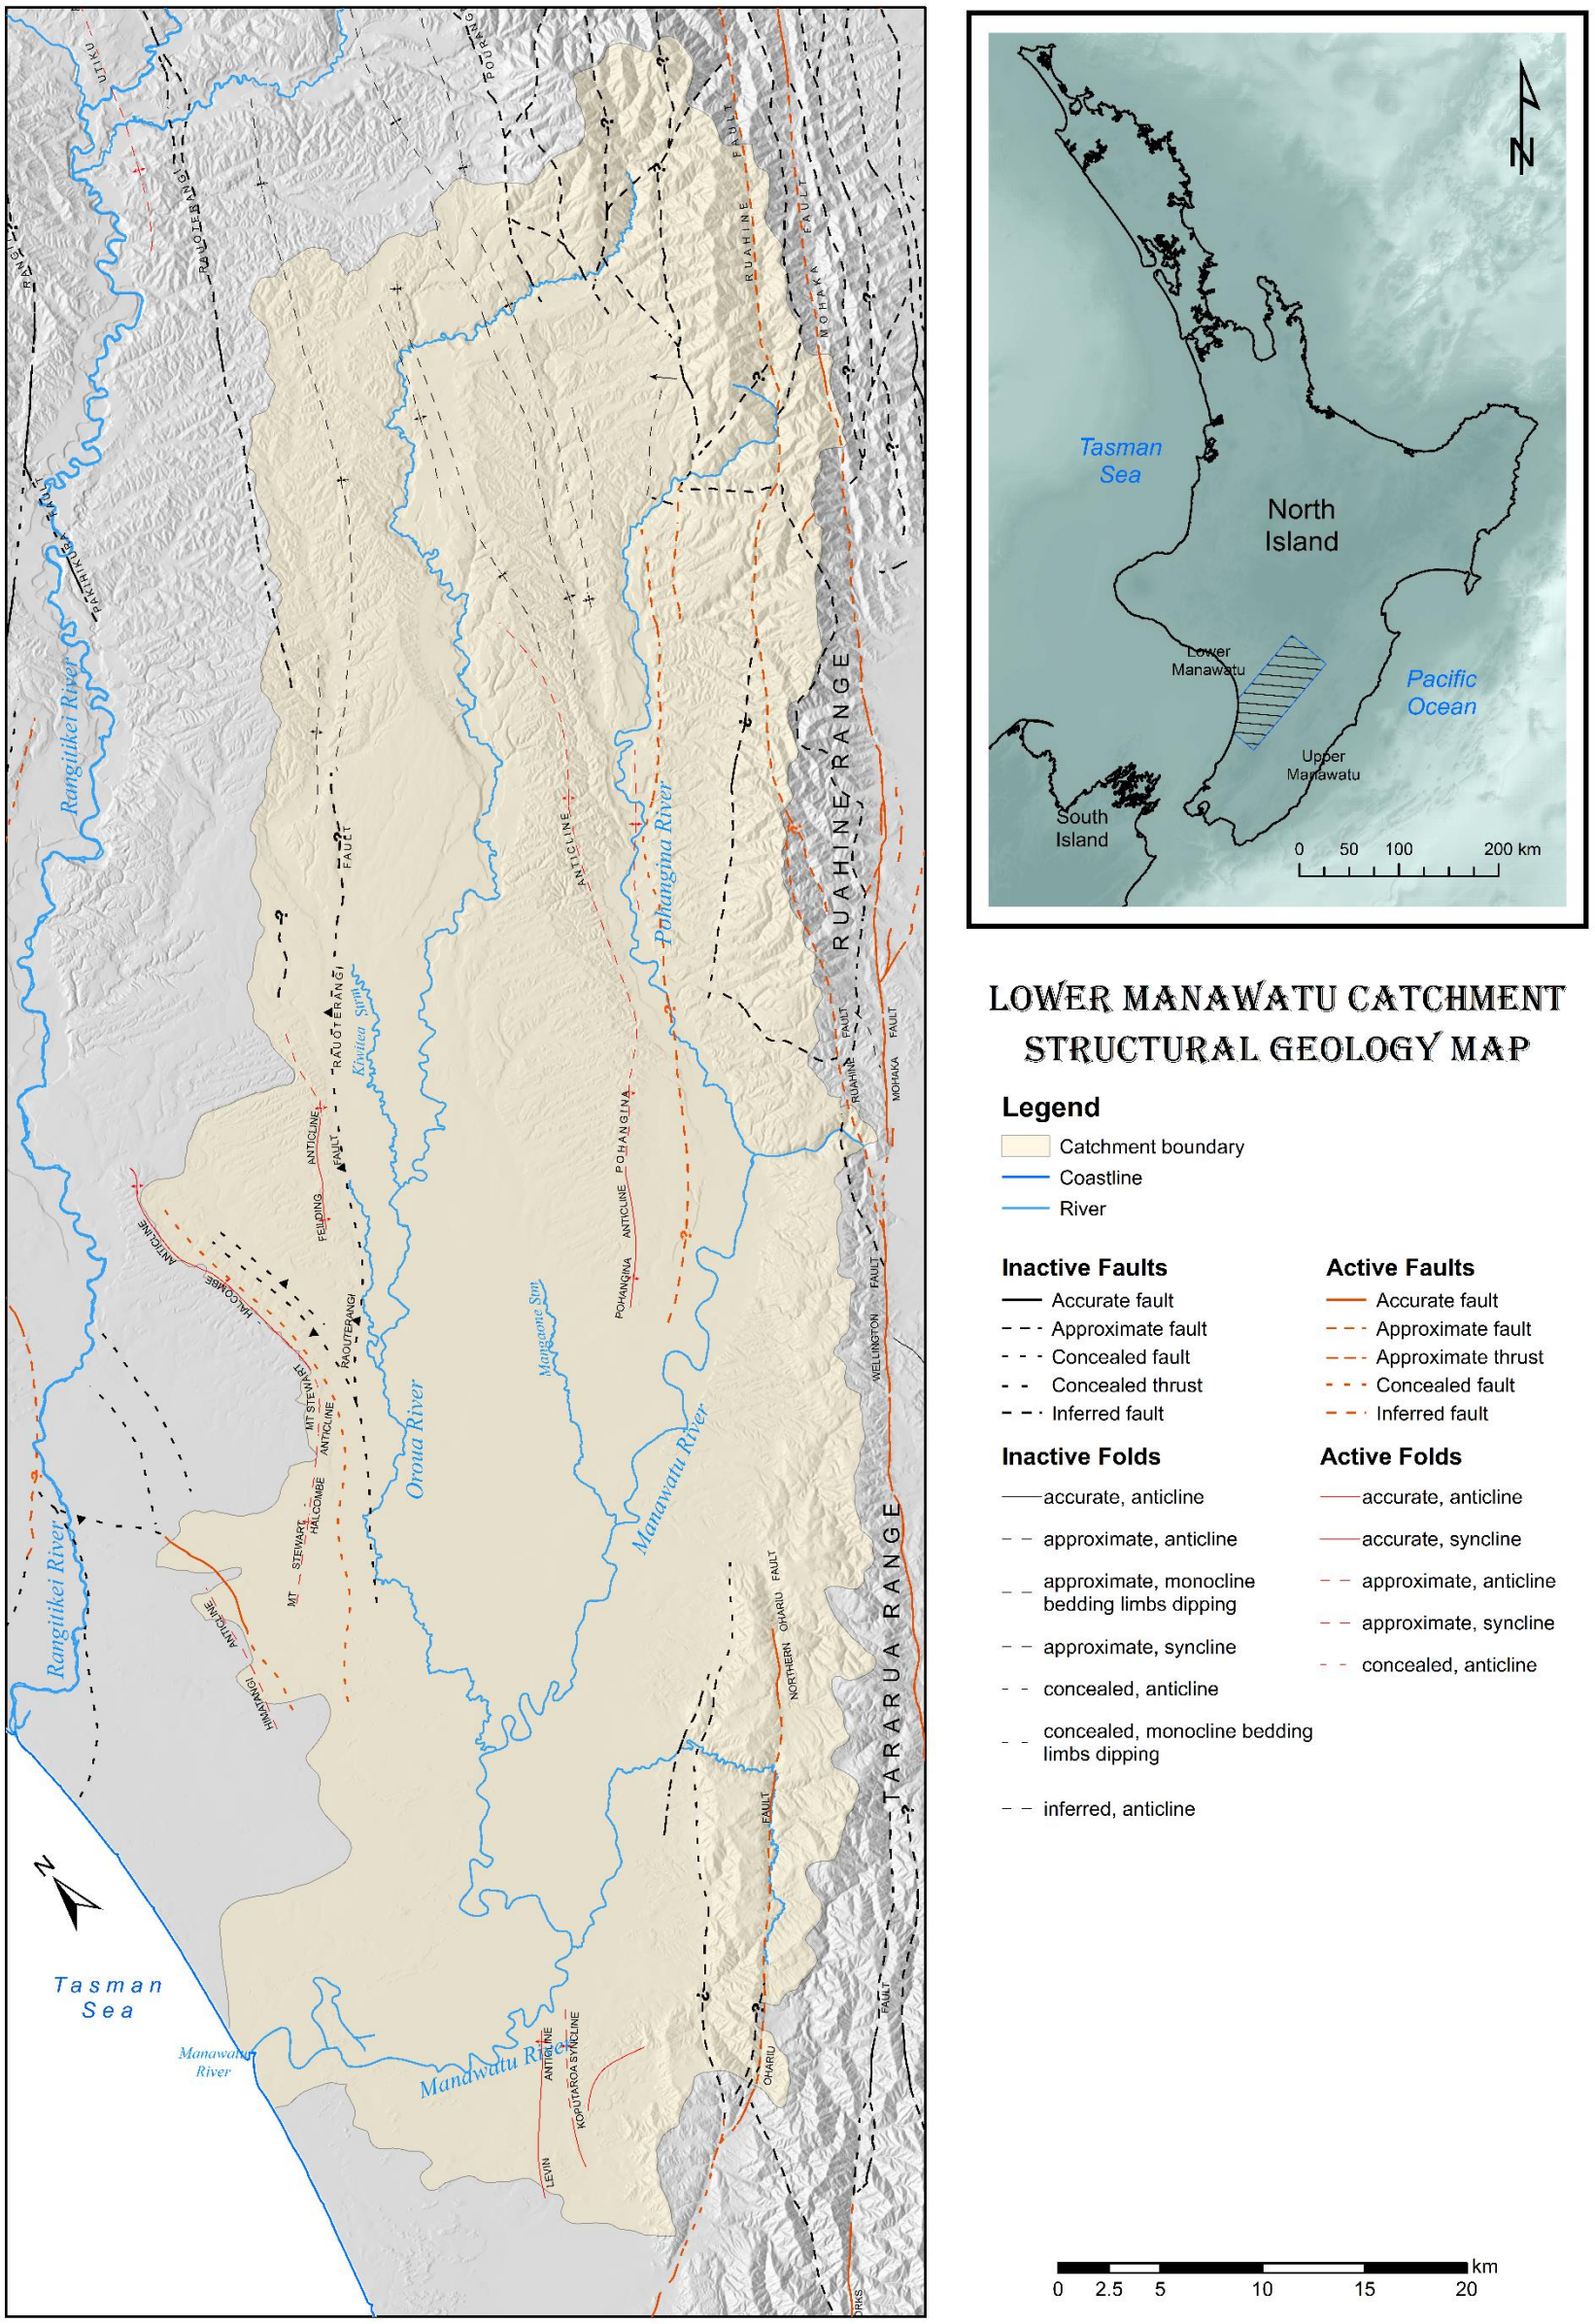

Figure 3-8. Structural geological map for LMC and surrounds based on digital QMAP data (Heron, 2014).

3.5.1 Subduction interface

The shallowly west-northwest-dipping fault that separates the Pacific and Australian plates at depth lies about 15 km beneath the Wairarapa coast and 25-30 km beneath Palmerston North (Figure 3-5). Deposits on top of the Pacific Plate to the east are being scraped off on the leading edge of the Australian Plate, and underplated beneath the east coast of the Wairarapa. While the plates slide easily, one across the other to the east of the Wairarapa coast, they are locked from beneath the Wairarapa coast to beneath the western side of the ranges. Strain associated with the relative motion of the two plates accumulates in the locked portion of the subduction fault and is released periodically as large earthquakes. Deformation at the surface associated with plate convergence over a long period of time has resulted in broad (long wavelength) patterns of deformation at the earth's surface, notably uplift of the Wairarapa coastal ranges, development of the Wairarapa-Pahiatua basins, uplift of the Tararua and Rimutaka ranges, and perhaps development and eversion of the Wanganui Basin.

During the Middle-Late Quaternary period, uplift rates within the axial ranges accelerated exceeding 1 mm/y (Kamp, 1992; Pillans, 1986) but rates vary spatially owing to broad warping and tilting and varying deformation histories of individual fault blocks (Heerdegen & Shepherd, 1992).

3.5.2 Faults and Folds

There are many active upper plate structural features within the study area (Figure 3-8). Figure 3-9 shows the style of deformation that might be expected near faults and folds in the LMC area.

Te Punga (1957) described the Wanganui Basin anticlines in detail. He considered them young features with high uplift rates, in the order of 8 mm/y. He hypothesised that folding could not have begun until after deposition of Haweran sediments. Melhuish *et al.* (1996) argues that this is incorrect, as folding has been going on for at least three million years.

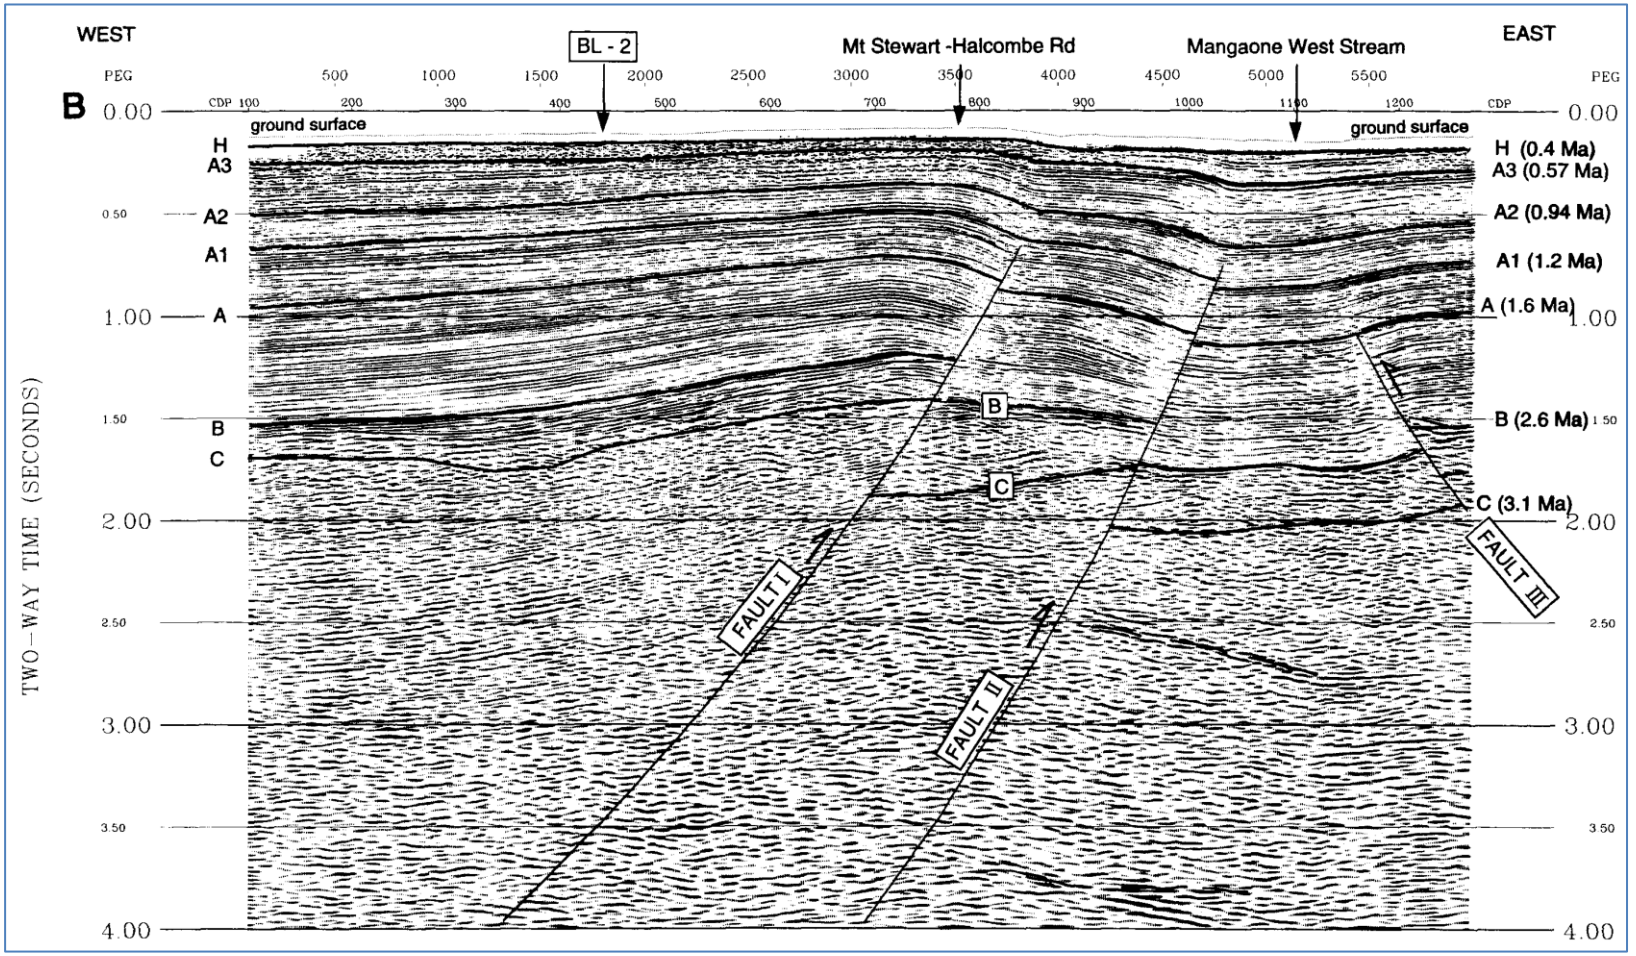

Figure 3-9. Interpreted seismic line from Melhuish *et al.* (1996) across the Mt Stewart-Halcombe Anticline and associated faults indicating the style of deformation that might be expected near at least some of the other faults and folds in the LMC area.

Wellington Fault

The Wellington Fault is one of the major dextral strike-slip faults in the North Island. Its location is known to the south of the south Wellington coast, and it traverses all the way to the Bay of Plenty, changing only in name and reducing slightly in long-term slip rate. The vertical component of slip on the Wellington Fault is largely responsible for the development of the Tararua and Ruahine ranges during the last c. 1–1.5 Ma[16]. Near the ground surface, the fault plane dips steeply but dip probably decreases at depth (listric), dipping to the west. The fault plane probably extends right through the upper (Australian) plate and bottoms out on the subduction interface.

Ruahine Fault

The Ruahine Fault is a western splay of the Wellington Fault, and as such is likely to be largely dextral strike-slip in character. The fault splays from the Wellington Fault near the Manawatu Gorge and traverses north through the middle of the Ruahine Range.

Northern Ohariu Fault

Another of the large, active dextral strike-slip faults of the North Island Fault Belt, the Northern Ohariu Fault is believed to be a northern extension of the Ohariu Fault in the Wellington area. It enters the Tararua Range at the Ohau River near Levin and can be mapped through the upper Tokomaru catchment to the top of Kahutarawa Road. Its location, if present, is unknown to the northeast.

Pohangina structure/Pohangina Anticline

There is good evidence for a fault and series of folds down the Pohangina River on the eastern side of the Pohangina Anticline (Begg *et al.*, 2005). Based on geological reconnaissance and seismic data, a fault has been marked down the Pohangina River (exposed in the river near Pohangina) (Anderton, 1981; Carter,

[16] Ma: million years.

1972; Feldmeyer *et al.*, 1943). The nature of the fault is poorly understood, although associated folding strongly suggests that it is active (Begg *et al.*, 2005).

Mt Stewart–Halcombe fault/Anticline

Melhuish *et al.* (1996) reported on a seismic reflection profile across the Mt Stewart–Halcombe Anticline clearly showing the relationship between west-dipping reverse faults and the folds of the Manawatu area (Figure 3-9). The profile imaged three faults, two associated with the Mt Stewart–Halcombe Anticline, and took in the west flank of the Feilding Anticline as well. The faults associated with the folds sometimes penetrate to the surface, but in many places are only indicated by the location of the fold axis. The anticline and its associated fault may be related to the fault named Rauoterangi Fault by Feldmeyer *et al.* (1943) and Anderton (1981) (see also Journeaux *et al.*, 1996; Lamarche *et al.*, 2005; Naish & Kamp, 1995). According to Melhuish *et al.* (1996), Mt Stewart–Halcombe Anticline is at least 25 km in length.

Feilding fault/Feilding Anticline

The Feilding Fault is a splay of the fault associated with the Mt Stewart–Halcombe Anticline, and the Feilding Anticline may be similarly related to the Rauoterangi Fault.

3.6 Physiographical setting

The geology and geomorphology in the LMC are products of tectonic–climatic interplay (Heerdegen & Shepherd, 1992). On the periphery of the Manawatu coastal plain, the long-term uplift rate of the Last Interglacial Tokomaru Marine Terrace over the past 120,000 years is estimated at 0.35 mm/y (Hesp & Shepherd, 1978). However, the terrace is tilted along its length and laterally towards the Manawatu coastal plain, implying lower rates of uplift on the plain than at the rear of the terrace, which onlaps against the Tararua Range (Clement, 2011). According to Clement (2011), research suggests that the rates of uplift near the LMC coastline ranges between of 0–0.06 mm/y since the Last Interglacial whereas the average uplift rate over the past 18,000 years has been about 0.5 mm/y further inland in the

Manawatu Valley area. The Manawatu coastal plain lies in a zone of subsidence albeit a zero rate of tectonic movement is suggested for the Manawatu through the Late Quaternary (Gibb, 1983; Pillans, 1986; Villiaxns, 1991).

The LMC plunges in a south-westerly direction. The upper part of the catchment comprises interfluves and river valleys whereas the lower part consists of nearly flat and flat plains. Figure 3-10 portrays a cross-sectional profile through the lower part of the interfluves-river valleys area in the LMC. The figure shows the restriction of river valleys between local active folds and is helpful for identifying potential groundwater recharge and discharge areas.

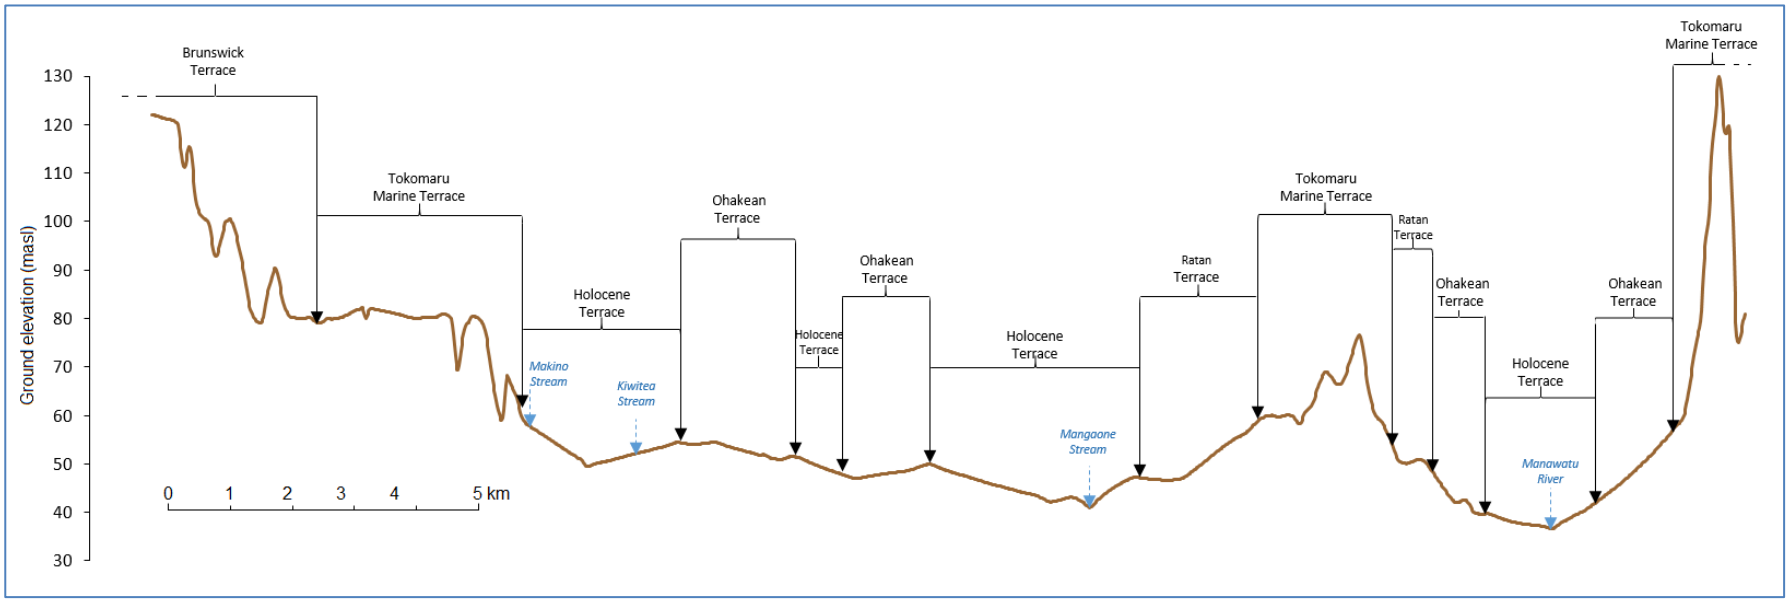

Figure 3-10. Cross-sectional profile through the lower part of the interfluves-river valleys area in the LMC. For location, see Figure 3-1.

3.7 Landforms

Physiographical setting manifested as landforms influences the potential of geological material to host groundwater. In particular, slope strongly affects the apportionment of precipitation water into surface runoff and groundwater recharge. The steeper the land the higher the proportion of precipitation water that turns into runoff at the expense of groundwater recharge. In addition, relative elevation of land defines its hydrogeological setting. Typically, elevated land marks potential recharge areas and low-lying land coincides with groundwater discharge zones.

The landforms of the Manawatu have been investigated by a number of researchers, e.g. Cotton (1918), Rich (1959), Fair (1968), Hesp (1975), Heerdegen (1982), Clark (1989), Heerdegen and Shepherd (1992), Kenny and Hayward (1993 & 1996), Sloss (2006), N. S. Wang and Grapes (2008) and Clement *et al.* (2009). Nonetheless, a systematic, quantitative landforms classification method would suit the purposes of this study better than classifications presented in previous studies. Therefore, the methodology developed by Hammond (1954 & 1964) was adopted in this thesis to categorise the study area's landforms. Hammond (1954 & 1964) method is based on the examination of relative elevation of land, specifically slope, local relief, tableland setting and profile. These terms are explained in the method implementation description below.

Hammond (1954 & 1964) method is widely used for local and regional-scale landform classification, with or without modifications, manually and GIS/computer assisted (e.g. Barka *et al.*, 2011; L. Brabyn, 2006; L. K. Brabyn, 1996; Dikau *et al.*, 1991; Naydenova & Stamenov, 2013). Wallace (1955) classified New Zealand landforms manually using a 1:1 000 000 base map and the Hammond (1954 & 1964) method with few modifications. To date, that work remains the only morphological classification of landforms for the entire of New Zealand despite computer hardware and software advances and the availability of better elevation data, including LiDAR coverage of many areas through the country. Influenced by the work of Dikau *et al.* (1991), L. K. Brabyn (1996) automated and slightly modified his method to

classify landforms in a land area of approximately 37,000 km², extending from shore to shore across the middle of the South Island.

3.8 Landform classification

The original Hammond (1954 & 1964) method depends on manual interrogation of topographical maps and uses a moving window of 9.6 km for physiographical analysis. In this thesis, the analysis was undertaken digitally using ArcGIS, NZSoSDEM v1 (Columbus *et al.*, 2011) and a 900 m diameter moving circle. The relatively small moving window is necessary to pick up catchment-scale changes in the landforms. Using 900 m diameter moving circle in the landform analysis does not provide enough high resolution for the characterisation of some local-scale features. For example, most of the narrow valleys with Holocene alluvial deposits are not characterised in their most suitable local-scale landform classes. This limitation in the used methodology may well extend to other small-scale features but is inevitable in catchment-scale studies such as this research. A description of the analysis parameters and steps is provided below.

Slope

Slope is the percentage of area occupied by gentle slope within 900 m radius around the cell. Hammond (1954 & 1964) specified 8% as the threshold for gentle slope. Slope is used to define how flat or steep the terrain is according to the criteria outlined in Table 3-2. It was calculated through:

1. Loading the 15-m resolution digital elevation model *[DEM_study_area]*
2. Calculating slope in percent rise for each pixel *[Slope_percent_rise]*
3. Reclassifying cells into gentle slope (code = 0) and steep slope (code = 1) *[Slope_steep]*
4. Reclassifying DEM_study_area to 1 value (code = 1) to enable counting them *[Cells_total]*
5. Counting the steep sloping cells (slope > 8%) within 900 m radius around each cell *[Cell_steep_slope_count_900m]*

Table 3-2. Land slope classes (adapted after Dikau *et al.*, 1991).

Percent of neighbourhood over 8% of slope	Slope Class
0 – 20%	400
21% – 50%	300
51% – 80%	200
>81%	100

Table 3-3. Land relief classes (adapted after Dikau *et al.*, 1991).

Change in elevation	Relief Class
0 – 30 metres	10
31 – 90 metres	20
91 – 150 metres	30
151 – 300 metres	40
301 – 900 metres	50
>900 metres[17]	60

6. Counting all the cells within 900 m radius around each cell *[Cell_all_count_900m]*
7. Calculating percentage of steep slope within 900 m radius around each cell *[Slope_steep_percent_900m = 100xCell_steep_slope_count_900m ÷Cell_all_count_900m]*
8. Classifying slope for each pixel according to the criteria outlined in Table 3-2 *[Slope_classes]*

Figure 3-11a presents a map of the calculated slope for the LMC.

Local relief

Local relief is the difference between the maximum and minimum elevation within 900 m neighbourhood around the cell. It is used to define terrain ruggedness (i.e. the complexity of its texture). Local relief was classified according to the criteria outlined in Table 3-3. It was calculated through:

1. Finding the maximum elevation in 900 m radius around each pixel *[Elevation_max_900m]*
2. Finding the minimum elevation in 900 m radius around each pixel *[Elevation_min_900m]*

[17] Class inexistent in study area.

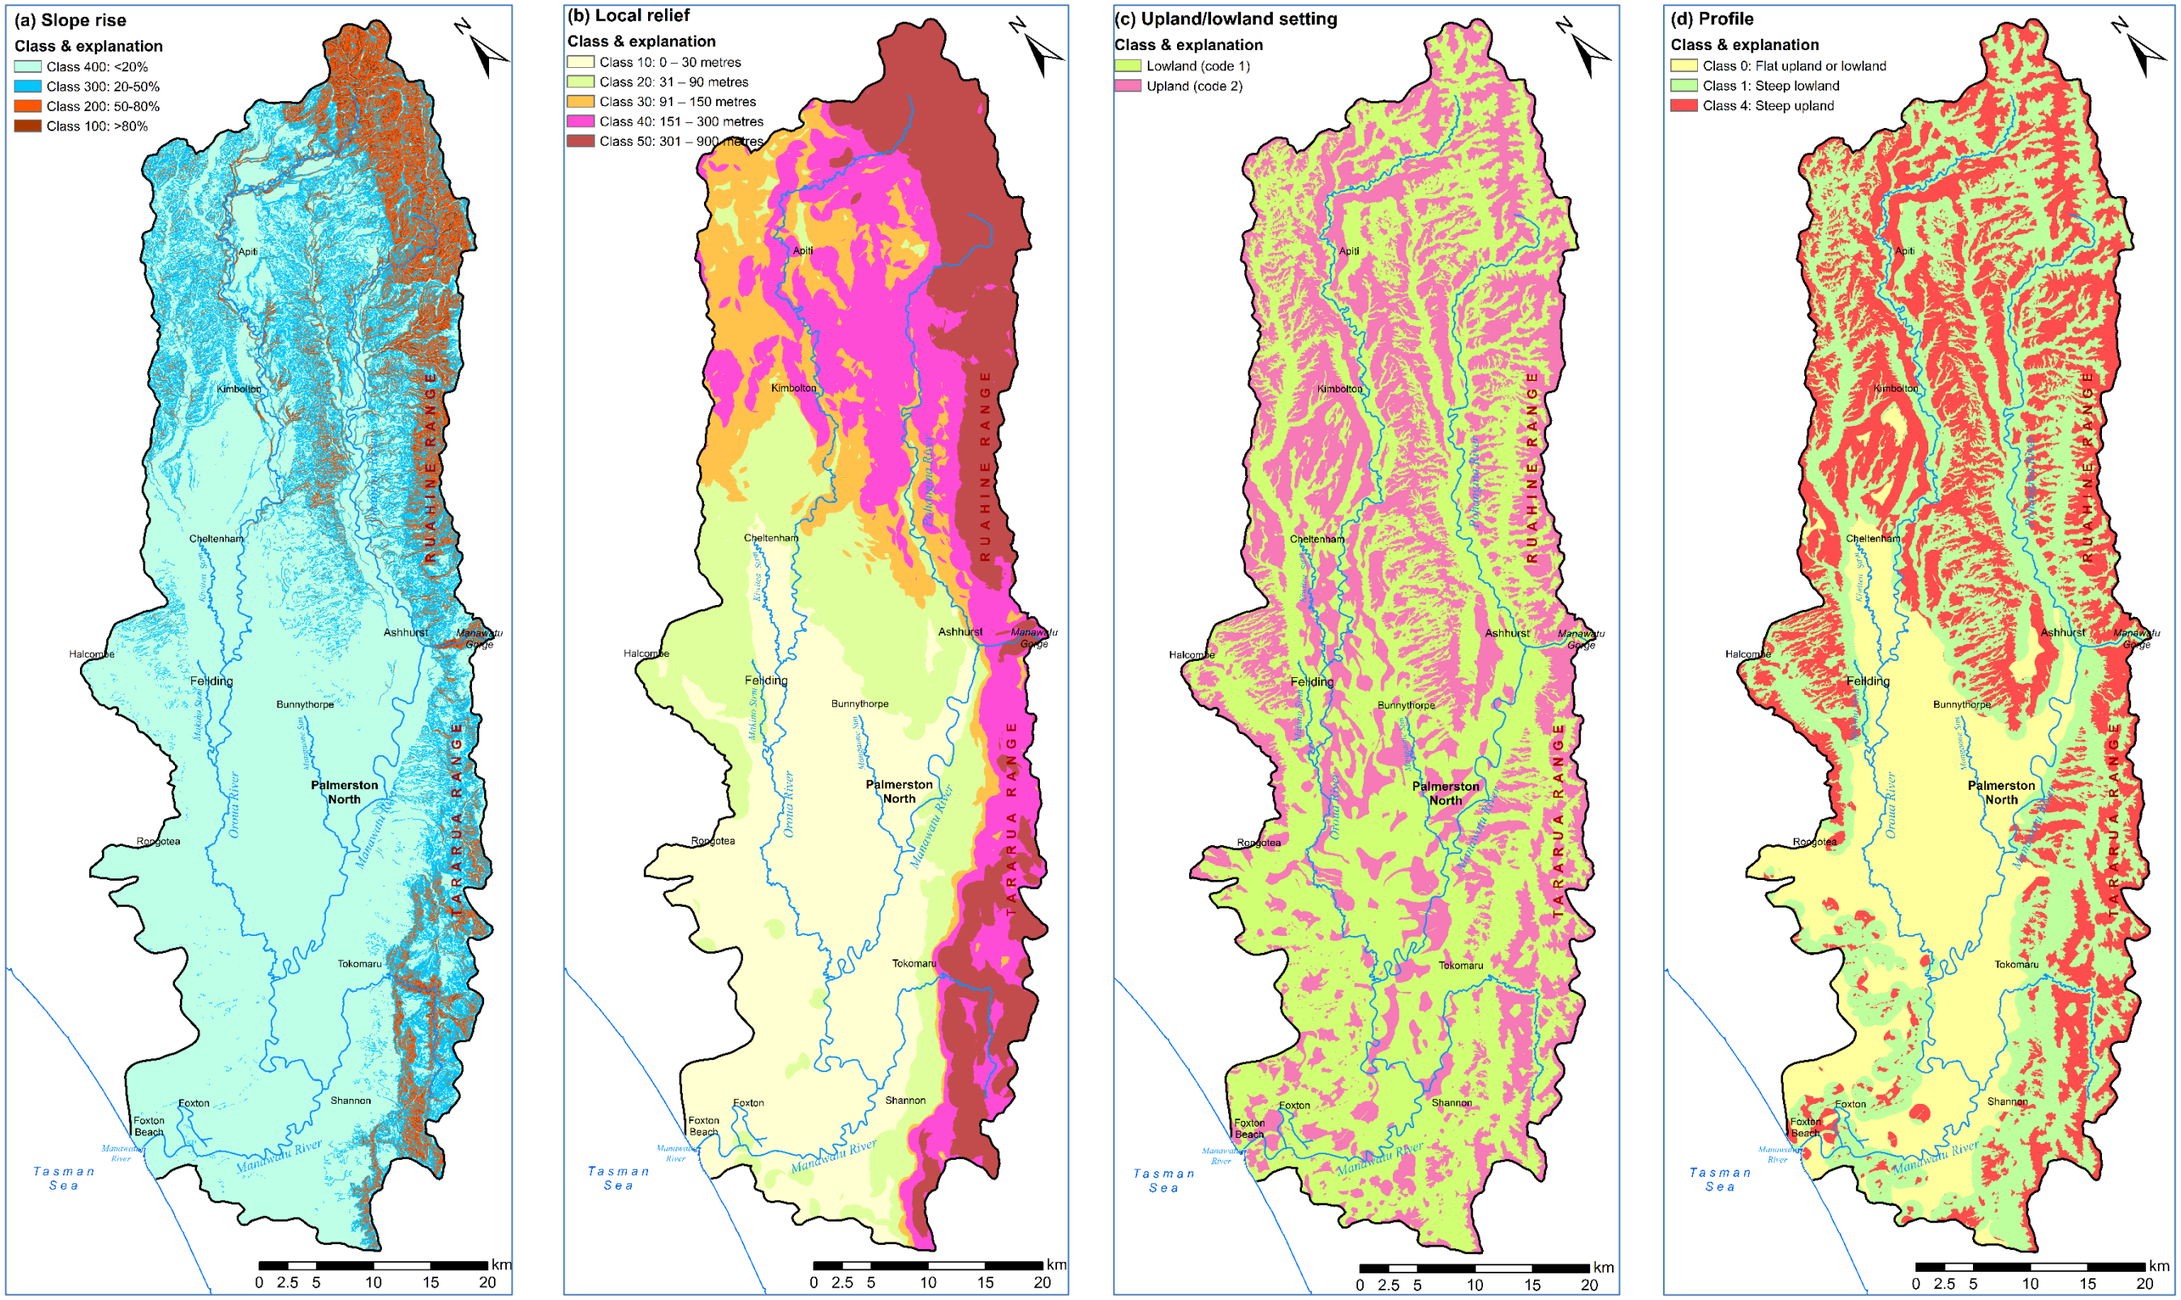

Figure 3-11. Slope rise, local relief, upland/lowland setting and profile calculations in 900 m radial moving window calculated from 15x15 m digital elevation model to enable landform classification using a modification of the Hammond (1954 & 1964) approach to suit local conditions and study objectives.

3. Calculating the local relief in metres *[Relief_in_metres = Elevation_max_900m – Elevation_min_900m]*
4. Classify local relief for each pixel according to the criteria outlined in Table 3-3 *[Relief_classes]*

Figure 3-11b presents a map of the calculated slope for the LMC.

Tableland setting

Tableland (upland/lowland) setting is determined by the difference between average local relief and elevation as outlined in Table 3-4. The cell is classified as upland if the difference between its elevation and the maximum elevation within 900 m radius around it is less than half of the local relief. Otherwise, the cell is classified as lowland. It was calculated through:

1. Calculating upland or lowland parameter [Low_up_parameter = if(abs(Elevation_Max_900m – DEM)) < (0.5xRelief_in_metres), then 2, else 1)]

Figure 3-11c presents a map of the calculated slope for the LMC.

Table 3-4. Upland/lowland classification (adapted after Dikau *et al.*, 1991).

Criteria	Classification
maximum elevation – cell elevation ≥ 1/2 local relief	Lowland (code 1)
maximum elevation – cell elevation < 1/2 local relief	Upland (code 2)

Profile

Profile is used to determine tableland areas. It is a calculation of the percent area of gently sloping terrain within upland and lowland areas within 900 m radius according to the criteria outlined in Table 3-5 *[profile_class]*. Figure 3-11d presents a map of the calculated slope for the LMC.

Table 3-5. Land profile classes (adapted after Dikau *et al.*, 1991).

% of neighbourhood over 8% slope	Class if in lowland area	Class if in upland area
50%<	0	0
50%-75%	2	3
>75%	1	4

According to the criteria presented in Figure 3-12, landform classes were determined in the LMC using the above noted parameter values (Figure 3-13). This exercise resulted in too many landform classes, which makes it unsuitable for hydrogeological purposes. Accordingly, similar landforms were grouped together and the LMC has been categorised into five landform types, namely: (1) high hills and low mountains, (2) open and moderate hills, (3) irregular plains, (4) plains with some relief, and (5) nearly flat plains (Figure 3-14). The landform classification proposed in this thesis is compatible to that of (Wallace, 1955) and (L. K. Brabyn, 1996).

Figure 3-12. Hammond (1954 & 1964) landform classification method criteria.

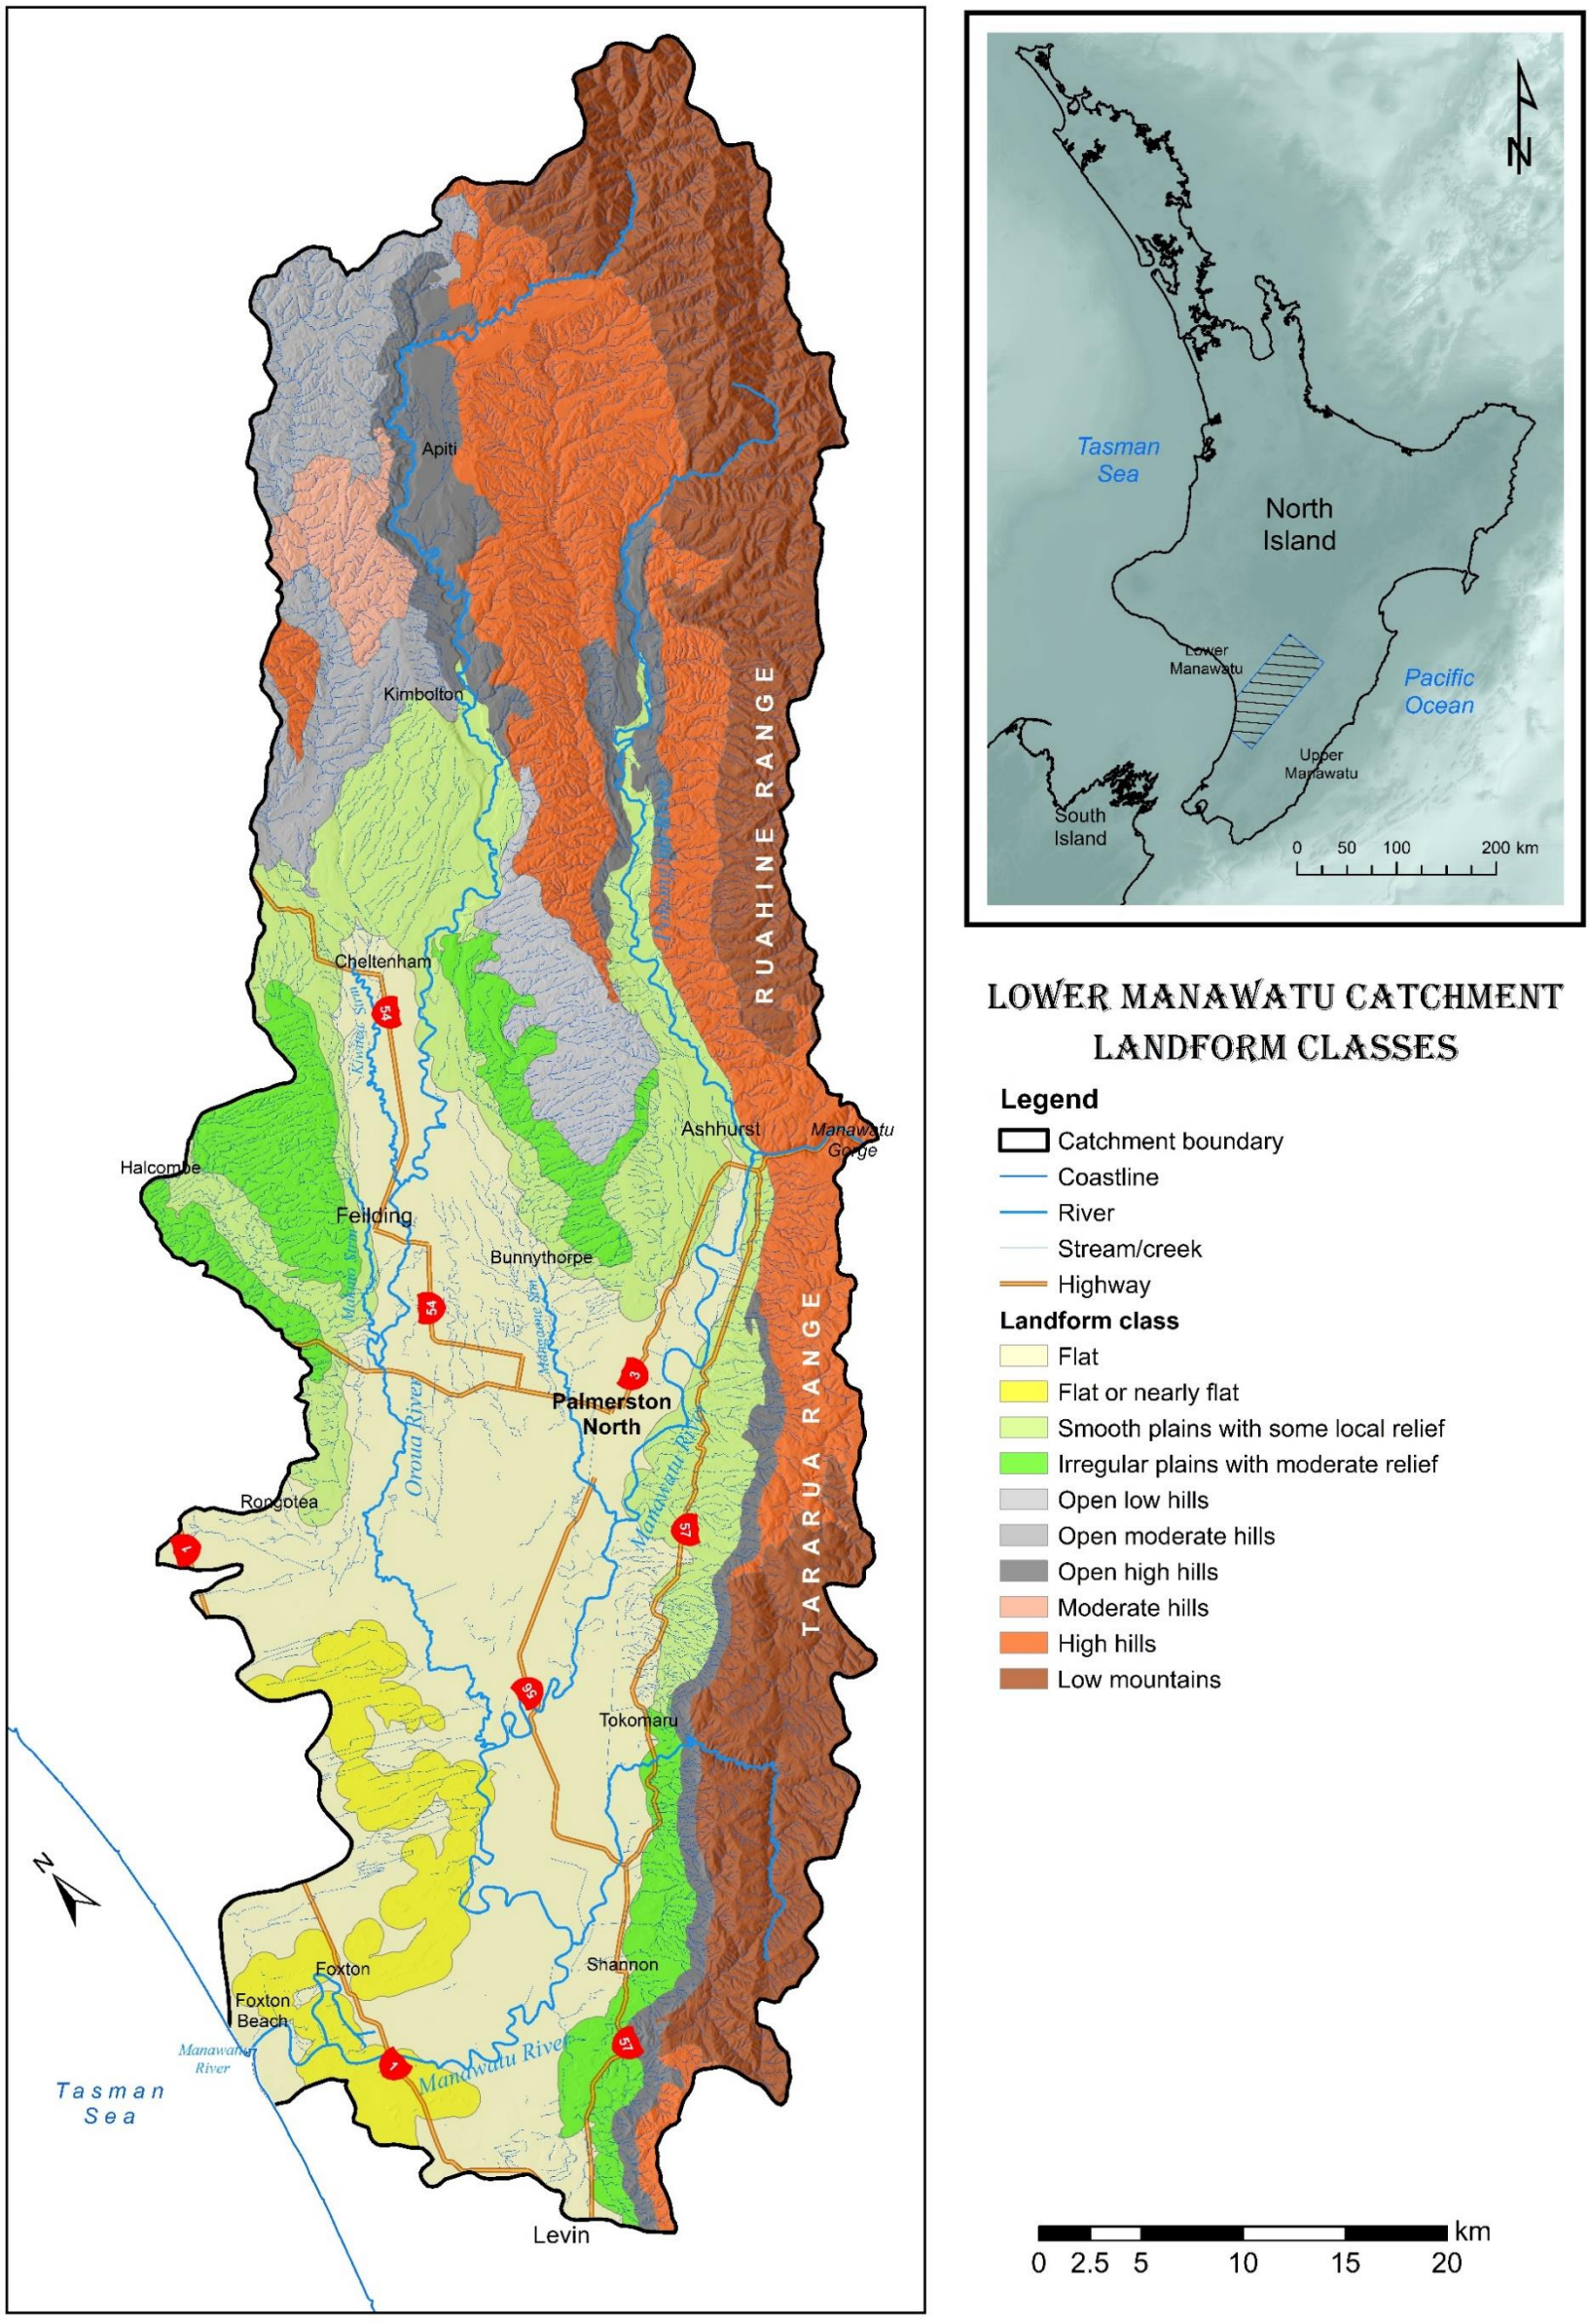

Figure 3-13. Landform classes calculated using the Hammond (1954 & 1964) method with modifications to suit local conditions.

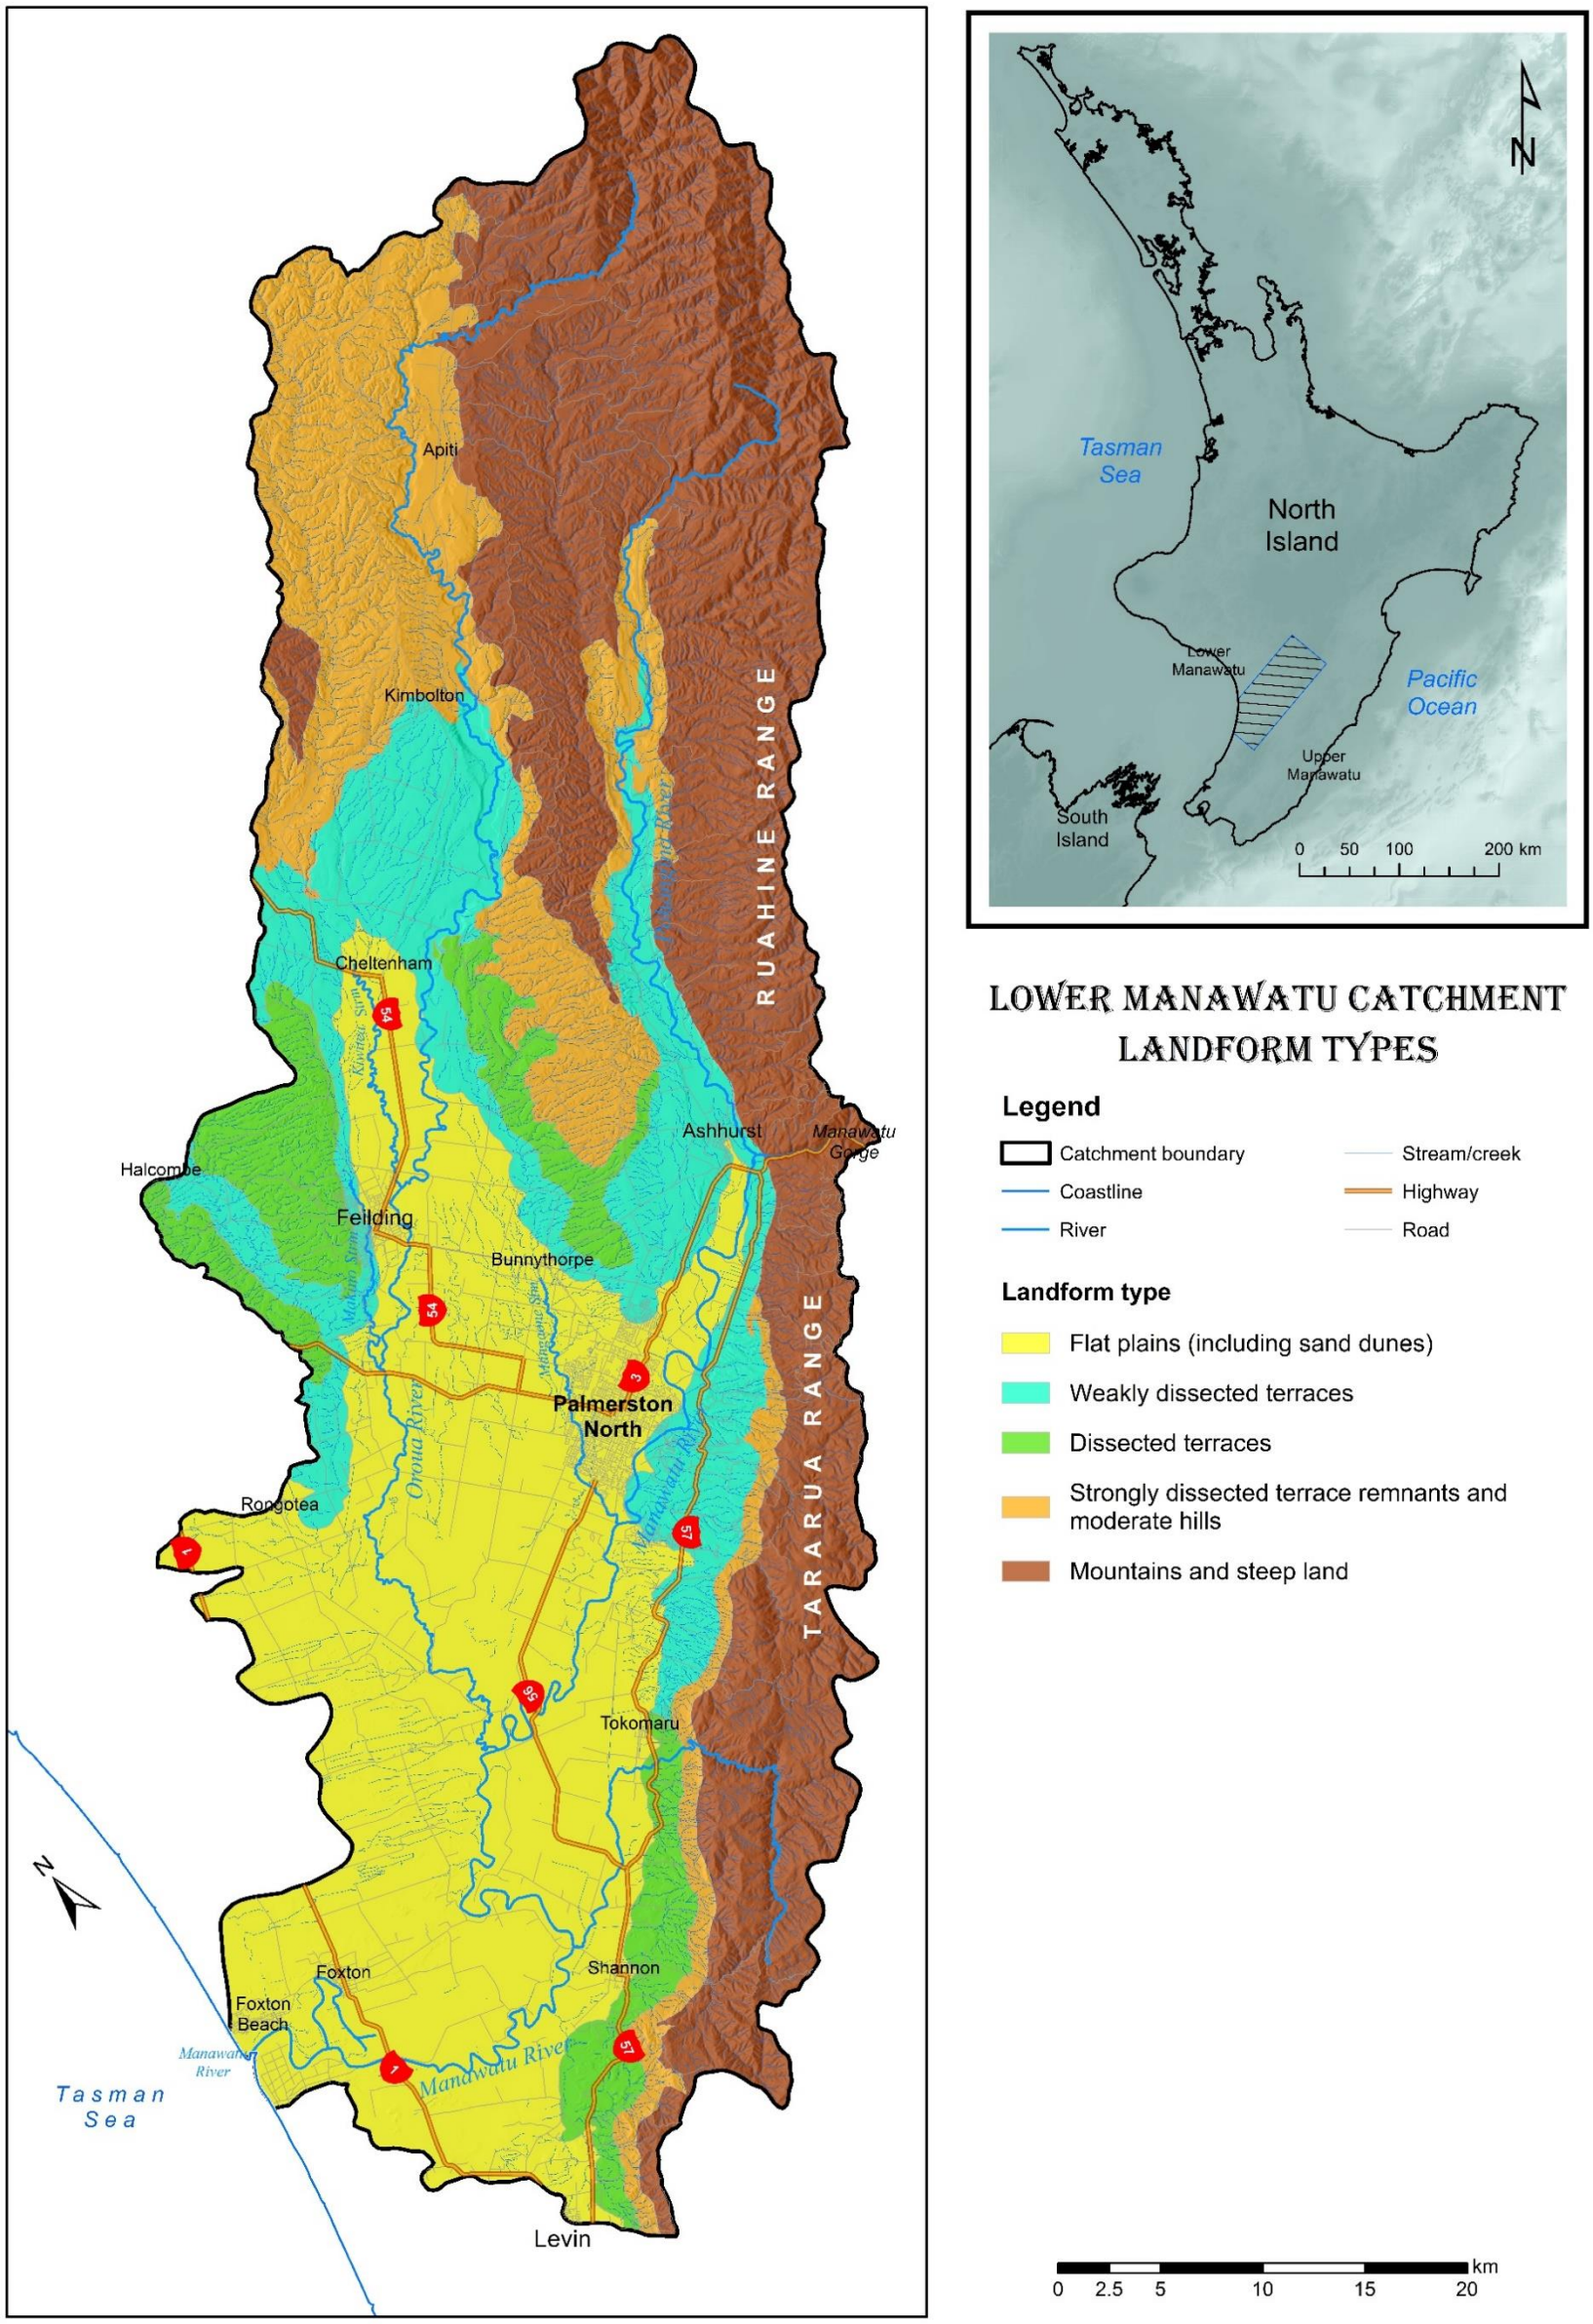

Figure 3-14. Landform types in the LMC.

3.9 Landform types

Begg *et al.* (2005) note that landforms in the LMC are exclusively geologically young, the entire area, from the coast to the top of the axial range at the Manawatu Gorge, having emerged from the sea in less than the last million and a half years.

3.9.1 Mountains and steep land

883 km²; 33% of LMC area

This landform type combines the low mountains, high hills and moderate hills landform classes delineated in Figure 3-13. It is situated in a structurally complex region, traversed by a multitude of folds and faults (Figure 3-14). Northeast-southwest trending mountains and steep land that form part of the North Island's axial ranges dominate the eastern landscape of the LMC (Figure 3-14). The mountains include the Tararua and Ruahine ranges which define the LMC's south-eastern boundary. The mountains are mainly underlain by Torlesse greywacke basement rock (Figure 3-2). In the upper part of the LMC, high, steep hills abut the mountains and extend in the north-eastern area of the catchment. There, the steep hills are mainly underlain by Plio-Pleistocene rocks.

The Manawatu River is an antecedent drainage feature that has maintained its original course through the uplifting of the axial ranges over the last million and a half years. It has incised its gorge through the high hills, separating the Ruahine Range to the north from the Tararua Range to the south. Steep greywacke bluffs enclose the gorge on either side.

In the north-eastern part of the catchment, the mountains achieve a maximum elevation of just under 1,700 metres above sea level (masl). The elevation of the basement rock drops in the area between the Ruahine and Tararua ranges where they are classified as high hills in Figure 3-13, but mountains and steep land in Figure 3-14. An increasingly intact remnant of an ancient erosion surface is preserved as land elevation descents from the high part of the crests of the Tararua and Ruahine ranges toward the Manawatu Gorge. Begg *et al.* (2005) describe it as

a gently folded surface (fold axis aligned northeast–southwest) of gentle relief, with relatively steep north-western and south-eastern flanks. They note that the basement rock underlying this surface is deeply weathered to about 10 m depth in places, and is overlain by loess and soil coverbed sequences. They also note that in the Saddle Road area on the northern side of the Manawatu Gorge, the surface is capped by marine and non-marine deposits less than 1.5 million years old.

The mountains and steep land region are dominated by an extensive dendritic drainage pattern (Figure 3-14). In dendritic drainage patterns, tributaries meet at low angles and branch in a random, tree-like pattern. They form on sloping land of erodable impervious or non-porous rocks or sediment, forming V-shaped valleys. They normally form on homogeneous rock masses with equal resistance to erosion in all directions, i.e. rock that contains no relatively weak layers (Zarour, 2017). In the low mountains area, the main streams and gullies are aligned nearly perpendicular to the structural grain whereas they run parallel, or sub-parallel, to it in the high hills area. Rivers in the eroded part of the ranges are typically steep and the landscape is deeply dissected.

The low mountains and the high hills landform classes are grouped together as a single landform type due to their similar surface water drainage patterns and geological structure characteristics (Figure 3-14). Geomorphological and geological settings of this part of the LMC do not indicate it contains important aquifers.

3.9.2 Strongly dissected terrace remnants and moderate hills

≈ 402 km²; 15% of LMC area ≈

Strongly dissected terrace remnants and moderate hills landform type comprises the open high hills, open moderate hills and open low hills. Although strongly deformed, the area of this landform type is much less structurally complex than the mountains and steep land (Figure 3-14).

This landform type is characterised by dendritic drainage patterns developed on Plio-Pleistocene marine sediments that were deposited in the Wanganui Basin, which have subsequently been faulted, folded, tilted and uplifted. Overall, relief and dissection increase inland, and valley profiles are V-shaped. In some places, more resistant sand beds, shellbeds or landslide-prone mudstone within the siltstone and sandstone marine deposits result in lines of steep V-shaped gorges or gently undulating belts traversing the landscape (Begg *et al.*, 2005). The area of this landform type has abundant colluvial sediment. Late Last Glacial fan deposits (Q2f) cover a strip of this landform type to the south and Early Quaternary alluvial deposits (eQa) bury this landform type land to the north (Figure 3-14 and Figure 3-2). Last Glacial and Holocene alluvial sediment in this area is limited in extent to narrow river valleys and is thin, not exceeding a few metres in thickness. Geomorphology and geology suggest that exploitable aquifers are unlikely to be present in areas of this landform. Most importantly, surface water drainage density in the area is classified as high to very high (Figure 3-15). Nonetheless, visual inspection of the Mangapikopiko Stream floodplain area near Apiti that is situated on Last Glacial terraces shows relatively low local surface water drainage density. The underlying geology and the relatively low surface drainage network density in the Mangapikopiko Stream floodplain area denote good local groundwater resource potential.

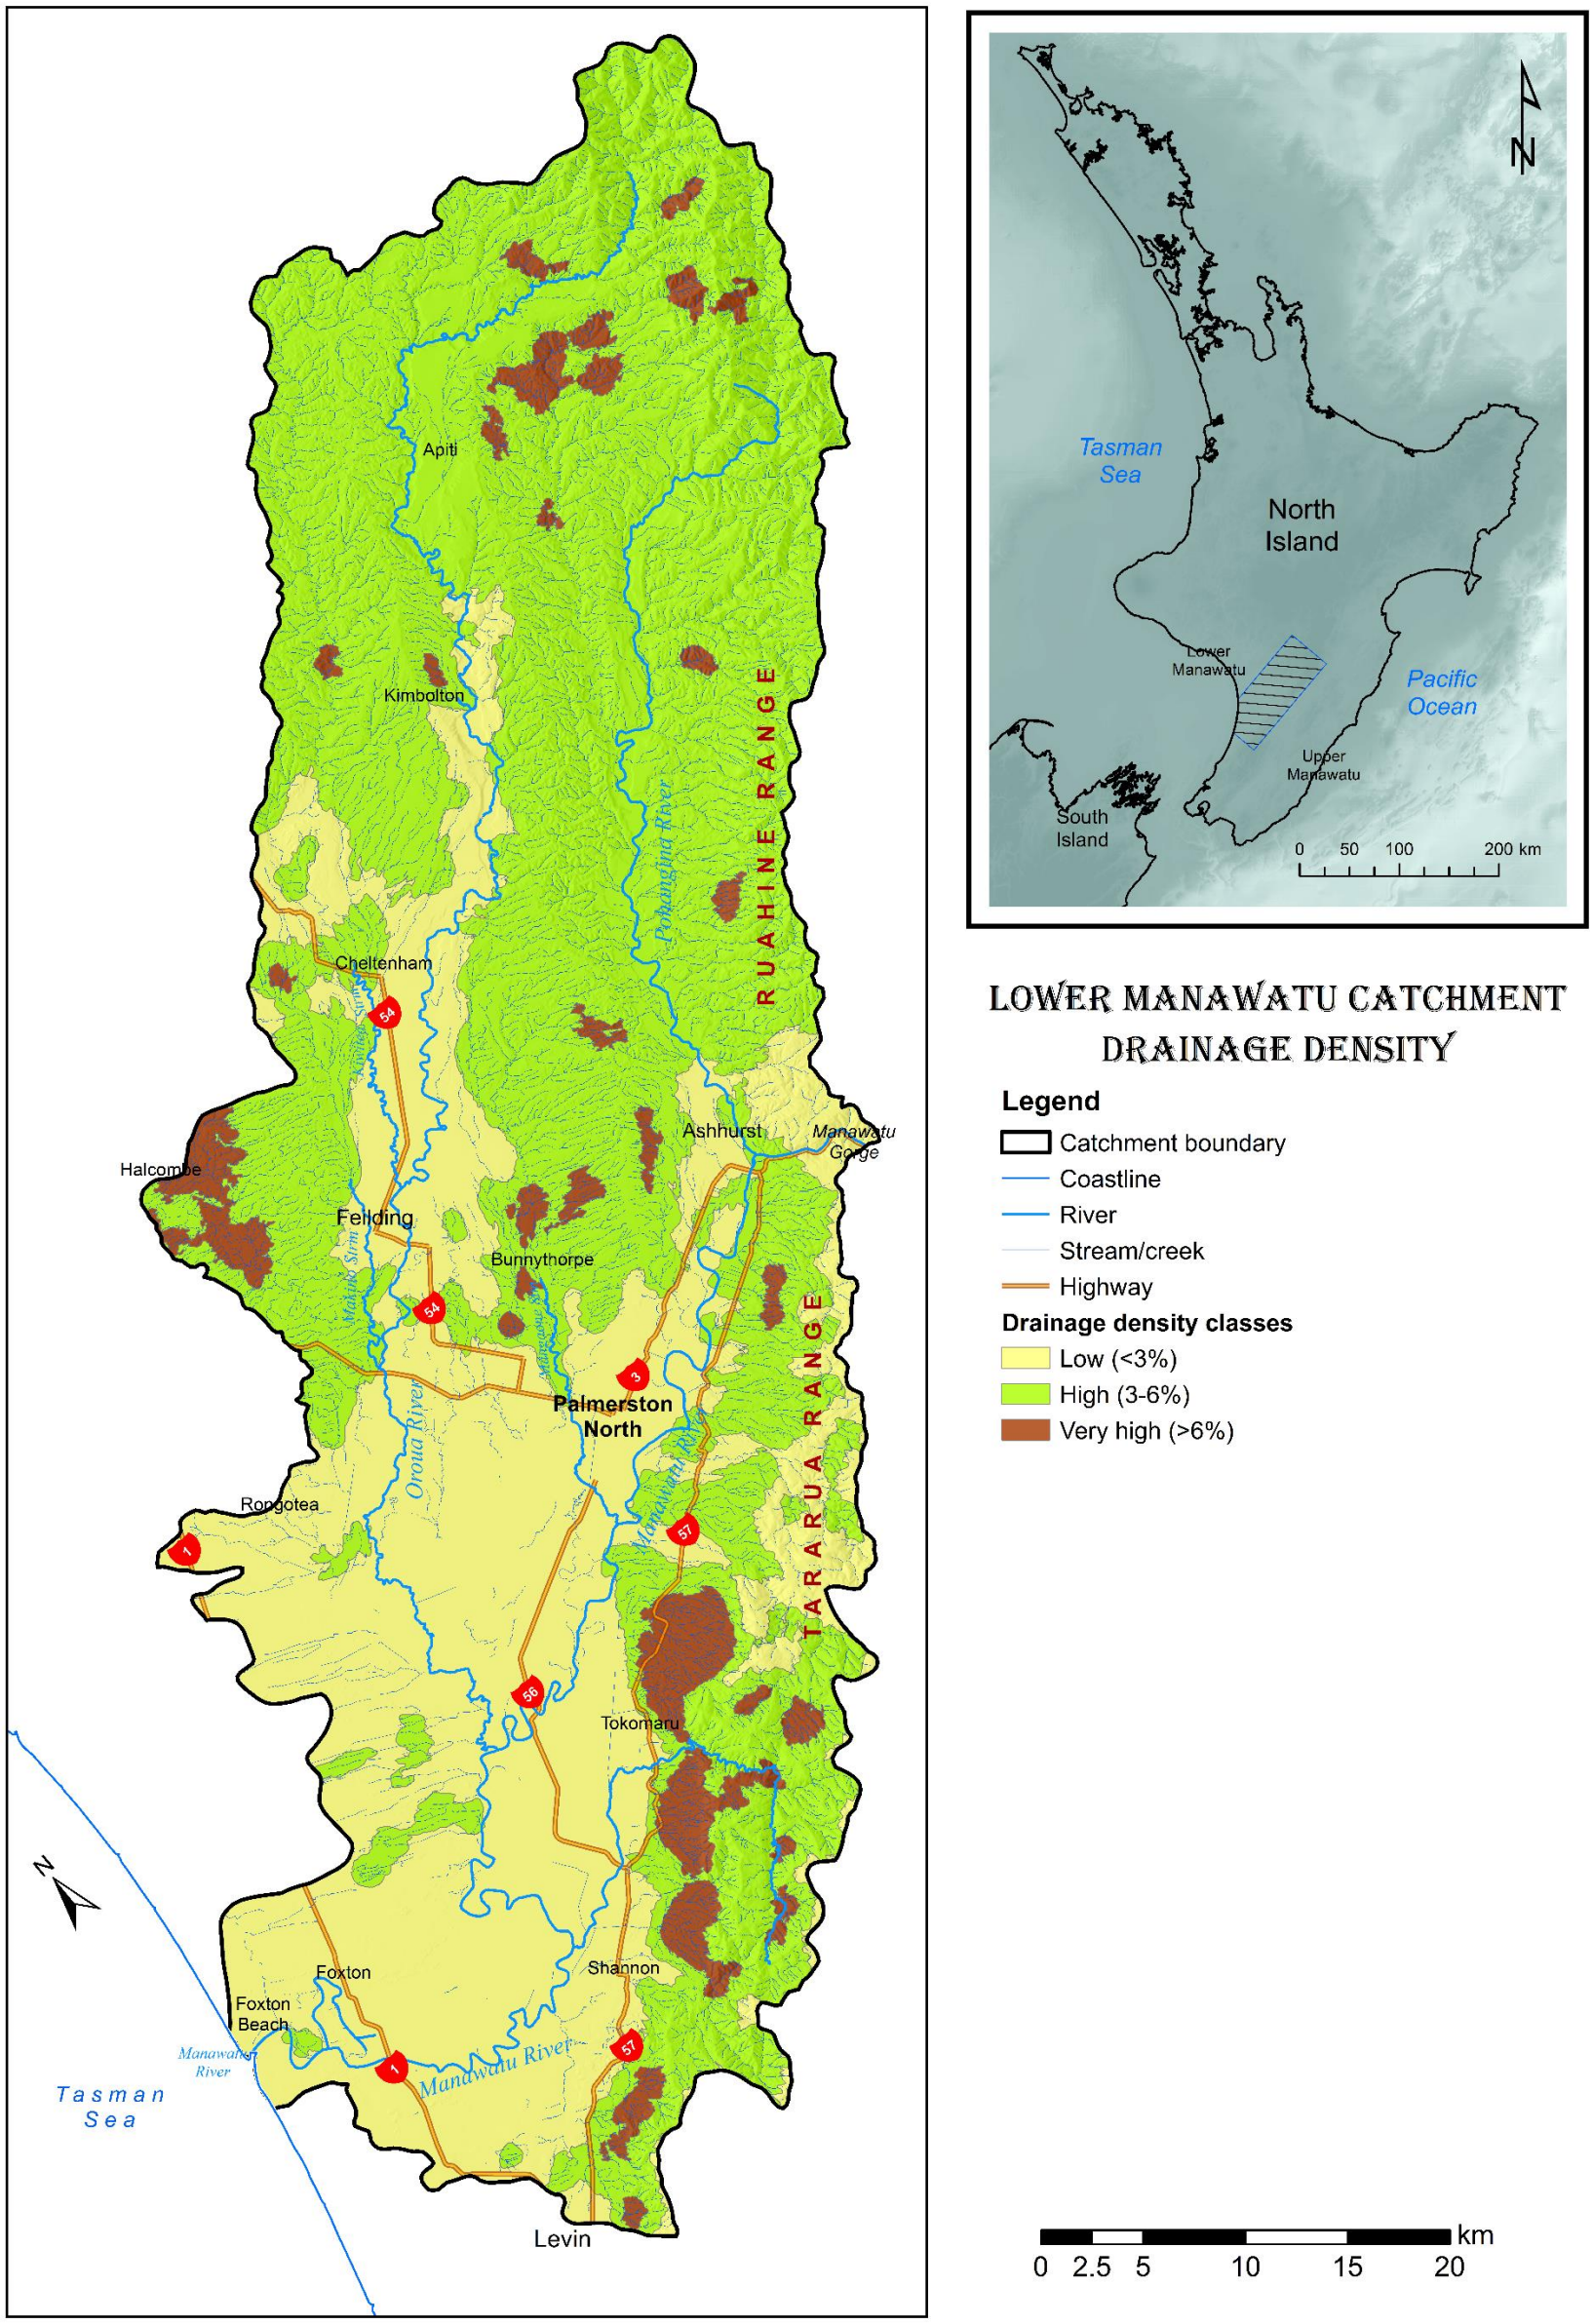

Figure 3-15. Surface drainage density in the LMC.

3.9.3 Dissected terraces

≈ 180 km²; 7% of LMC area ≈

The dissected terraces landform type delineated in Figure 3-14 corresponds to the irregular plains with moderate relief landform class in Figure 3-13. Its area nearly exclusively consists of elevated Quaternary interglacial marine terraces (Q11b, Q9b, and Q5b; Figure 3-14 and Figure 3-2). These terraces cover areas that are folded and tilted, with gently dipping to rolling topography. Generally, such sediments in the Wanganui Basin form the toes of interfluves that separate the valleys of the southwest-flowing major rivers, e.g. the upper part of the Oroua River system from the Pohangina River to the east and the Rangitikei River to the west. The crests of the interfluves are marked by anticlines.

The dominant lithology in the sediments forming these terraces is sand. Gravely horizons are present in them, reflecting stadial periods and beach environment deposition. The fine-grained lithology of the sediment or sediment matrix significantly reduces their hydraulic conductivity. In addition, these terraces are characterised by high local relief (Figure 3-11b), which favours surface water runoff over groundwater recharge. This is reflected in very high to high density dendritic surface water drainage, which signals low groundwater recharge. These sediments are expected to have low groundwater resource potential.

3.9.4 Weakly dissected terraces

≈ 356 km²; 13% of LMC area ≈

A flight of weakly dissected terraces skirts the LMC flat plains from the northeast (Figure 3-14). This landform type corresponds to the irregular plains with moderate relief and the smooth plains with some local relief landform classes in Figure 3-13. These terraces mainly consist of glacial periods alluvial deposits (Q10a, Q4a, Q3a, and Q2a) with some relatively low-lying Last Interglacial deposits (Q5b) forming marine terraces and Holocene age alluvial gravel in current river valleys.

Like all the above-mentioned landform types, dendritic drainage patterns characterise this landform type areas (Figure 3-14). However, this landform encompasses areas of high and low drainage density (Figure 3-15).

Last glacial alluvial sediment forming these terraces are fairly permeable and the terraces geomorphology is not as strongly biased towards surface water runoff as the previous landform types. Hence, these sediments can receive recharge from rainwater percolation and they can transmit sufficient water to allow them to be classified as aquifers. If hydraulic conditions permit, these sediments can also receive recharge from surface waterways. Therefore, they have good groundwater resource potential.

3.9.5 Flat plains

≈ 858 km²; 32% of LMC area ≈

An area of flat plains dominates the lower part of the LMC (Figure 3-14). This landform type consists mainly of the Oroua and Manawatu rivers floodplain. It also includes the area between Poroutawhao and the coastline, and both flanks of the Himatangi Anticline, which are covered by sand dunes (units Q1dm and Q1ds in Figure 3-2). Inactive sand dunes (Q1ds) are found closer to the shoreline. Sand dunes in the area reach a maximum elevation of 30 masl. They are mostly classified as flat or nearly flat landform in Figure 3-13.

The area is characterised generally by non-existent to low density surface water drainage network (Figure 3-14 and Figure 3-15). However, very high and high surface water drainage network density can be found in places within this landform type. Dendritic drainage is limited within this landform type to areas underlain by Last Interglacial and Last Glacial deposits. Holocene sediment covered areas are characterised by trellis drainage patterns. In trellis drainage, short tributaries meet long trunk streams at near right angles. The trunks are notably unconnected. In the trellis drainage patterned areas, consequent streams follow the dips and subsequent streams are parallel to strikes. Thus, short juvenile streams flow

towards the longitudinal centre of the LMC and join longer secondary streams and rivers that flow towards the coastline.

Trellis drainage pattern forms where surficial sediments overlie faulted and folded strata (Zarour, 2017). Hence, trellis drainage patterns on areas mantled by sand dunes possibly indicate that Holocene sand unconformably overlay structurally deformed sediment, probably Q5b or Q9b interglacial periods deposits. According to Begg *et al.* (2005), they are underlain by river silt, sand and minor alluvial gravel and incorporate inter-dune swamps.

Dune morphology varies from longitudinal dunes, barchan-style dunes to shore-parallel mounds, their shape probably influenced by topography and consequently, wind velocity (Begg *et al.*, 2005).

The sand dunes merge smoothly with the Manawatu River system alluvial plains. Begg *et al.* (2005) note that the Manawatu River floodplain is very low-lying, with the river meandering greatly in its course to the sea; the 20 m contour crosses the river bed almost 70 km upstream from the sea. As a result, all gravel in the Manawatu River bedload is lost well before it reaches its mouth. This is an important characteristic of the area because of its possible hydrogeological implications.

Strata underlying the flat plains are permeable and the area's surface water drainage pattern generally does not indicate that surface runoff is favoured over recharge. There is also evidence on groundwater-surface water interaction in this area. Hence, strata underlying this area have the potential to bear groundwater and serve as a resource for the environment and other purposes. This is proven by the area's well yields that are used for domestic and economical productive supplies.

3.10 Stratigraphy

In unconsolidated strata like the aquifer system in the LMC, stratigraphy and lithology are the most important geological controls on groundwater occurrence

and flow (Hiscock, 2009). Hence, a clear stratigraphical understanding is essential to this research.

The geological sequence in the Region can broadly be divided into three main divisions as suggested by Rich (1959):

1. well indurated and deformed rocks of early Mesozoic and perhaps late Paleozoic age
2. poorly consolidated, predominantly marine sediments of Plio-Pleistocene age with interbeds of glacial times alluvial deposits
3. Recent (Holocene) unconsolidated non-marine surficial deposits.

Rocks of the first division constitute an undermass that is separated by a regional extent major unconformity from the overlaying sedimentary cover, which comprise sediment of the other two divisions. This two-fold concept of undermass and cover is well established in New Zealand geological literature and is especially useful in structural and geomorphological interpretation. Rich's (1959) classification is well-suited to hydrogeological analysis purposes. Begg *et al.* (2005) and Zarour (2008) adopted a similar general stratigraphical classification approaches.

Figure 3-16 presents a simplified geological map for the LMC, in which the area's stratigraphy has been classified into seven units based on the information presented in Table 3-1. These stratigraphical units can be aggregated into the following four main stratigraphical groups, which are described in Sections 3.10.1 through 3.10.4:

1. Greywacke basement rocks
2. Plio-Pleistocene marine rocks
3. Middle-Late Quaternary glacial terraces and interglacial benches
4. Holocene alluvium and dune sands.

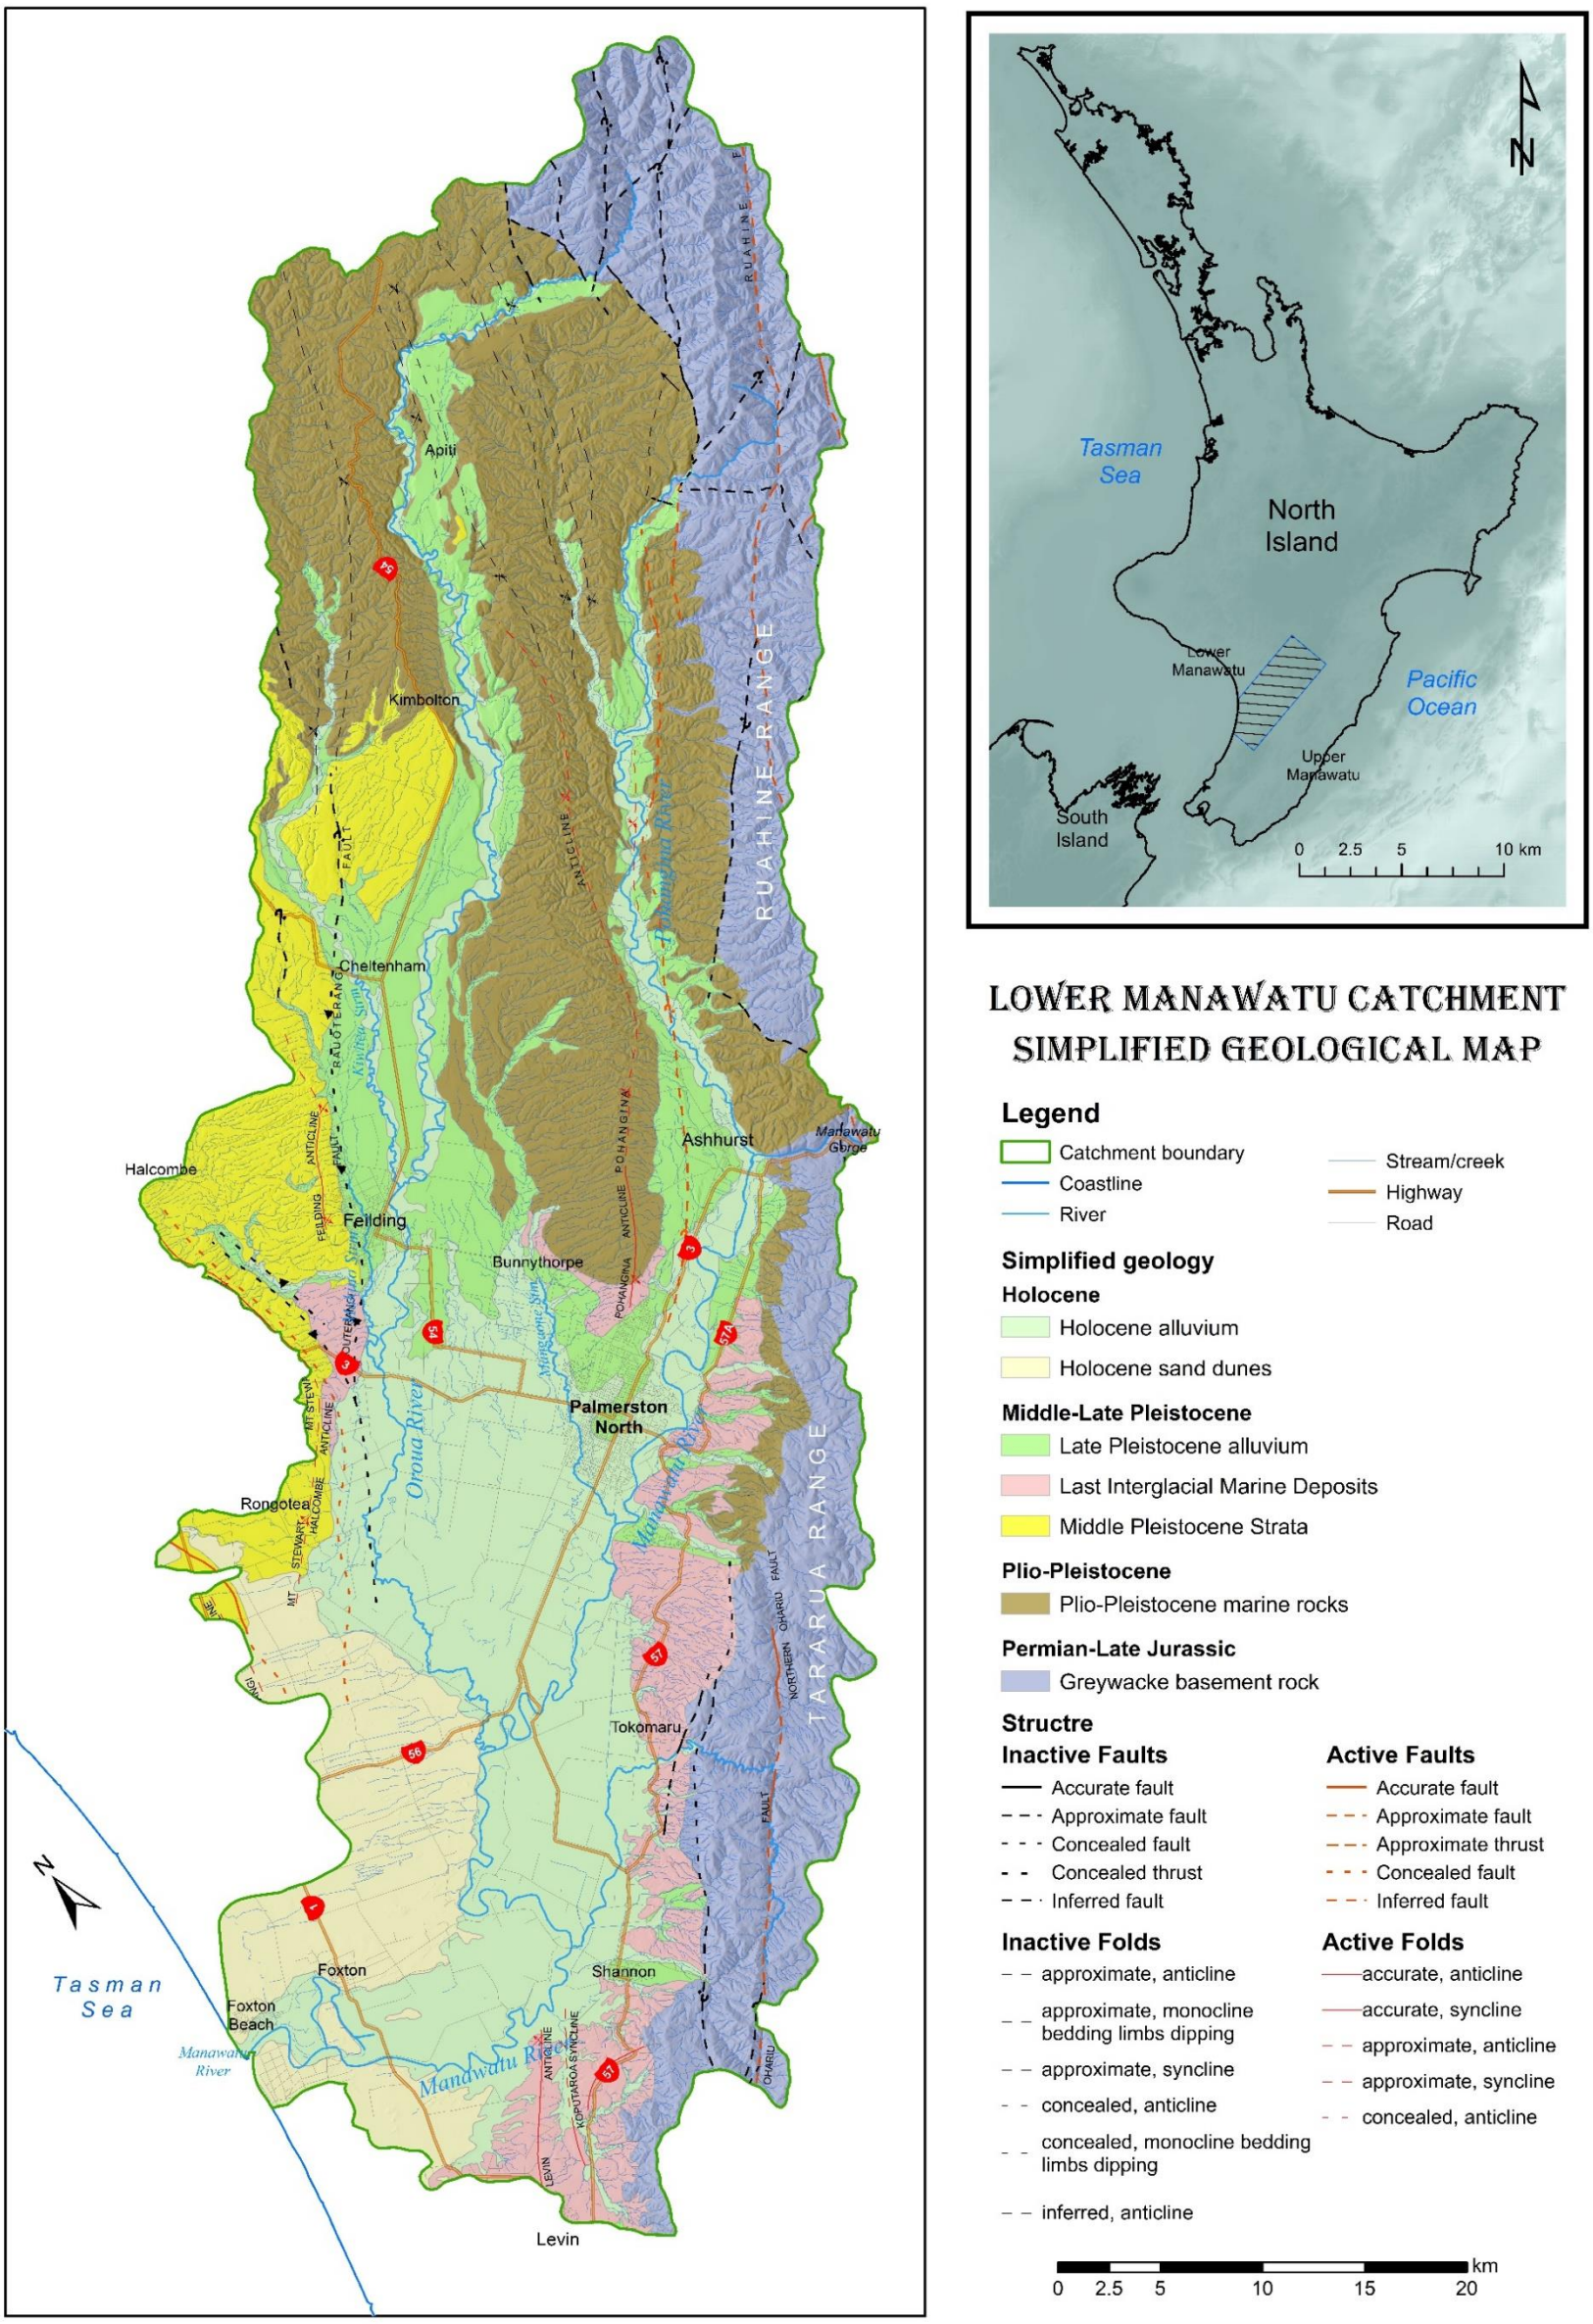

Figure 3-16. Simplified geological map for the LMC.

3.10.1 Greywacke basement rocks

Units **Ttt**, **Jtk**, **Te**, **Tev**, **Kep**, **Ktp**, **Ktw** in Table 3-1 and Figure 3-2.

Contemporary literature refers to this rock unit as the Torlesse Composite Terrane greywacke basement rather than undermass. Greywacke basement rocks undoubtedly underlay the North Island central ranges and all younger deposits in the LMC (Begg *et al.*, 2005). In the study area, exposures of these rocks are limited to the Ruahine and Tararua axial ranges and are best displayed in the Manawatu Gorge (Rich, 1959). These rocks occur at shallow depth in parts of the Horowhenua, at about 15 mbgl approximately midway between the foothills and the coastline, and they crop out offshore of Kapiti coast, forming the Kapiti Island (Zarour, 2008).

The thickness of the basement rock unit is unknown. It predominantly consists of unfossiliferous indurated quartzofeldspathic sandstone and interbedded mudstone. It also contains argillite with associated spilite and chert. Rare fossil occurrences within these rocks suggest they ranges in age from Permian to perhaps as young as Early Cretaceous, although they are mostly Triassic in age.

Rocks of this unit are commonly deformed, often showing several generations of folding and faulting (including bedding plane shear) and are now usually steeply dipping. Some rocks in this unit have been so thoroughly disrupted by ancient shearing that they consist of mixtures of blocks floating within a sheared mudstone matrix. These are known as melange and they commonly contain blocks of other rock types including basalt, chert and limestone.

Basement rocks commonly have mineralised cement. Therefore, they are impervious and impermeable. Consequently, they are not able to hold or transmit water except where they are weathered. Basement rock weathering generally ranges between low to moderate, but it can be extensive in places, possibly reaching up to around 10 mbgl.

3.10.2 Plio–Pleistocene marine rocks

Units coded **Pep**, **Pea**, **Pi**, **Pm**, **Pio**, **Pik**, **Pim**, **Pp**, **Puo**, **Pu**, **Pit**, **eQo**, **eQk**, **e-mQs**, **eQp**, **eQa**, **Q11b** in Table 3–1 and Figure 3–2.

The Wanganui Basin involves c. 4–5 km of Pliocene–Holocene sedimentary cover, which lies unconformably on basement rock. For the purposes of this thesis, a Plio–Pleistocene rock group is defined as rocks ranging in age from the Pliocene to the Castlecliffian Stage (OIS11).

Plio–Pleistocene rocks principally consist of marine deposits – mostly mudstone, siltstone, sandstone, pumiceous sand and minor limestone and conglomerate. Fine-grained strata in this rock unit are commonly described as papa by local drillers.

Plio–Pleistocene strata dip relatively gently south and southwest around the southern side of the Taranaki coastline. These rocks immediately underlie most of the land that is not designated as nearly flat and flat plains in the previous section (Figure 3–14). In places, northeast–southwest orientated faults cut the sequence (e.g. Kamp *et al.*, 2004; Naish & Kamp, 1995) (Figure 3–16).

These deposits are generally of continental shelf origin. A number of lithostratigraphical groups are incorporated within this unit. They include the Paparangi, Okiwa, Nukumaru, Maxwell, Okehu, Kai–iwi and Shakespeare groups. Paparangi, Okiwa and Nukumaru groups comprise principally marine mudstone and siltstone, with minor sandstone and limestone. The Maxwell Group is largely of non–marine origin, with lithologies ranging from shallow marine sand and estuarine silt to non–marine lignite and clay. The Okehu Group consists of siltstone and pumiceous sand (the Potaka pumice sand). The Kai–iwi Group consists of marine silts and sands, and the Kaimatira pumice sand. Marine fossils are common within

most of these units and indicate Late Pliocene to mid-Castlecliffian depositional age (c. 3.7 – 0.7 Ma BP[18]).

Due to sea level change during the Pliocene and Pleistocene times, few unconformities of relatively short duration can be found in the Maxwell, Okehu, Kai-iwi and Shakespeare groups. Nonetheless, this sequence is broadly conformable. It is regarded as one of the best onshore predominantly marine sequences of rocks of this age in the world (Carter & Naish, 1998b). In the Pohangina River catchment, these strata are faulted against and rarely unconformably overlie rocks of Torlesse greywacke basement (Begg *et al.*, 2005).

Siltstone and mudstone have high intrinsic porosity and very low primary permeability, rendering such strata in this unit as aquitards or aquicludes. Sandstone and pumiceous sand formations within this unit have significant intergrain pore space and good permeability, conglomerate has lower but reasonable permeability and mature limestone can have high secondary permeability due to dissolution and dolomitisation. However, relatively young age, structure, interfingering with silt and mud beds and topography generally diminish the potential for all strata in this unit to yield good amounts of water through wells. In addition, loess cover over most of the area underlain by this unit greatly limits its ability to receive recharge from rain and surface water. Consequently, rocks in this unit generally do not host important aquifers except in the Wanganui District where the city and surrounds depend on deep highly productive wells tapping Middle Nukumaruan age strata for their water supply. Middle Quaternary age rocks crop out in Kai-iwi and occur at about 700 mbgl under Wanganui City at relatively short distance down-dip of Kai-iwi.

[18] Before present.

3.10.3 Middle–Late Quaternary strata (Hawera Series)

Units coded **Q10a**, **Q9b**, **Q8a**, **Q6a**, **Q6f**, **lQa**, **lQl**, **lQf**, **Q5b**, **Q4a**, **Q4f**, **Q3a**, **Q3f**, **Q2a**, **Q2f** in Table 3–1 and Figure 3–2.

Haweran Stage sediments in this research are coded according to the QMAP convention. In this system, Quaternary age is designated in stratigraphical unit codes by the letter Q. Where the OIS during which the unit was deposited is known, it is indicated by its number and a suffix to denote the depositional environment, e.g. Q2a to symbolise alluvial OIS2 deposits. Sediments deposited during even numbered OISs relate to cool climatic periods and those deposited during odd numbered OISs relate to warm climatic periods, except for OIS3, which represents a warmer phase between cooler periods of the last glacial period. Where an OIS cannot be reasonably allocated, a prefix is used to delineate Late (l), Middle (m) or Early (e) Pleistocene age, e.g. mQf to signify middle-Pleistocene fan deposits. In this thesis, Early Quaternary refers to strata older than OIS10, Mid-Quaternary refers to unites deposited during the period OIS10–OIS6, and Late Quaternary refers to unites deposited in the Last Interglacial and last Glacial (OIS5–OIS2).

A flight of Middle–Late Quaternary age (Haweran Series) terrestrial and marine terraces flank river valleys in the LMC (Figure 3–2). They gradually diminish as they extend into the Manawatu Plains. The terraces consist of sediment relating to the period OIS10–OIS2, inclusive (i.e. c. 360–10 ka BP according to Pillans (1990) and Suggate (1990) stratigraphical classifications). Haweran Series deposits separate Castlecliffian Stage sediment from that of the Holocene (Fleming, 1953). The base of the Haweran Series is marked by the Rangitawa Tephra (350 ka BP), which lay within the OIS10 glacial period deposits (Beu, 2001). LMC terraces were created by tectonic and global climate change processes (Fair, 1968). Figure 3–17 schematically presents the stages of terrace development in the LMC. Pleistocene terraces in the Wanganui Basin are commonly mantled by sheets of loess relating to subsequent glacial periods.

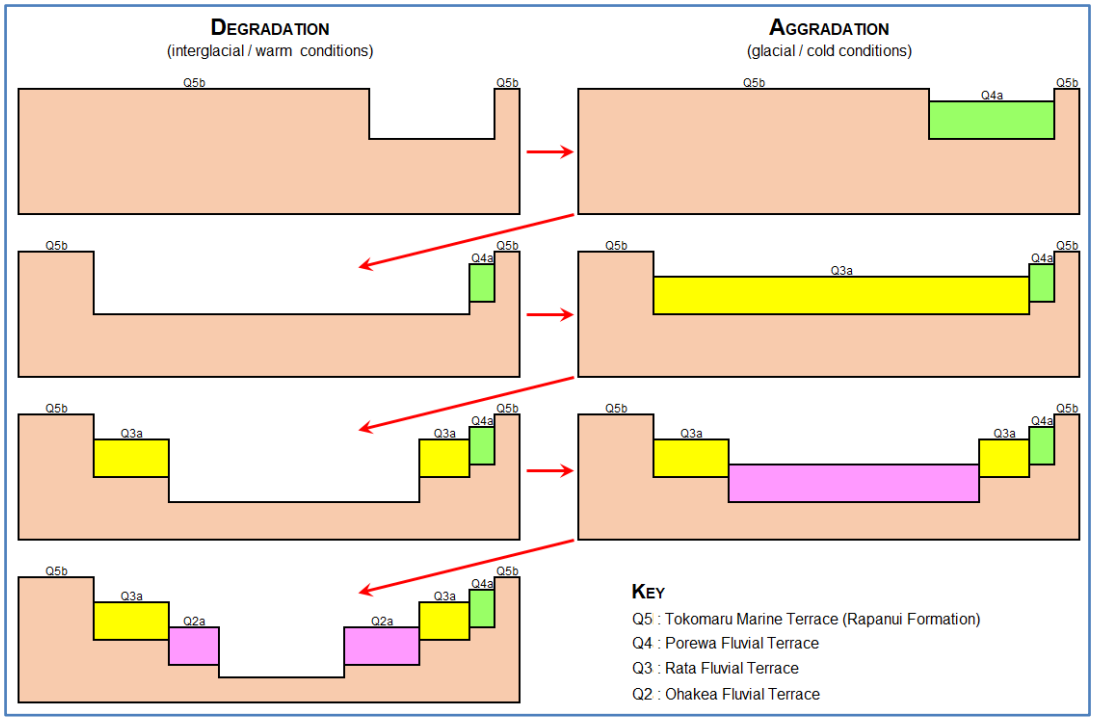

Figure 3-17. Schematic drawing illustrating the formation of terraces in the LMC (adapted after Fair, 1968).

Warm (interglacial) period deposits represent high sea level times during which marine deposition prevailed (e.g. **Q9b** and **Q5b**; Brunswick and Tokomaru marine benches, respectively). Now, these deposits constitute elevated marine terraces. Technically, where these sediments skirt the axial ranges, they from straths (bedrock terraces) rather than terraces because they are most probably eroded into greywacke basement rock. In contrast, terraces are elevated unconsolidated alluvium deposited by the same river that incised them.

Fluvial terraces are alluvial floodplain remnants formed as a result of river erosional downcutting, abandonment and lateral erosion of its former floodplains due to either changes in sea level, local or regional tectonic uplift; changes in local or regional climate, changes in sediment load, change in river flow, or a complex mixture of these and other factors. Alluvial terraces are remnants of cold climate period floodplains deposited when sea level (base level) was distant and lower. In the LMC, they relate to the Nemona Glacial period deposits (**Q10a**), Waimaunga Glacial period deposits (**Q8a**), Waimea Glacial period deposits (**Q6a**), and Otira Glacial period deposits (**IQa**, **Q4a**, **Q3a**, **Q2a**). During cold times, loose material

accumulated on steep slopes in the LMC due to aeolian, slopewash and downslope-creep deposition as colluvial deposits (e.g. **lQl** material). Alluvial fans (**Q6f**, **lQf**, **Q4f**, **Q3f**, **Q2f**) were built where small steep streams approached flattened surfaces and dump their bedload in fan-shaped deposits,

Alluvial terrace sediments of the Haweran Series generally consist of poorly to moderately sorted alluvial gravel with minor sand and silt. The older the sediment the more weathered it is. Quaternary terraces older than the Ohakea Terrace are commonly covered by loess. The loess cover is neither shown in the geological map (Figure 3-2) nor in Figure 3-17. Loess is discussed further in Section 3.13 because of the important role it plays in determining the ability of rainwater to percolate into underlying layers to replenish their groundwater reserves.

Steep alluvial and colluvial fan and landslide deposits are found in the LMC almost exclusively in areas classified as steep lowland (Figure 3-2 and Figure 3-11d). Fan deposits consist of very to moderately weathered, weakly consolidated, poorly sorted gravel, sand, silt and clay. Landslide deposits range from coherent shattered masses of rock to unsorted fragments in a fine-grained matrix. Fan and landslide deposits are characterised by low porosity and permeability due to their poor sorting. Their steepness and limited volume do not allow them to hold significant water.

Sediments underlying Brunswick and Tokomaru benches were deposited in shallow marine depositional environments. They consist of conglomerate, shellbeds, dune sand, silt and mud. These deposits are commonly mantled by loess and fan deposits. Loess cover restricts rainwater recharge to these layers, limiting their potential as water resources. In the Horowhenua, wells tapping **Q5b** sediment (the Otaki Sandstone[19]) can yield enough water for domestic supply purposes. Wells in the higher positioned Brunswick Terrace normally fail to produce useful amounts of water.

[19] Unit referred to as Rapanui Formation in other places.

Examination of drillers' well logs reveals common peat presence in interglacial deposits in the LMC. Peat is not normally deposited in shallow marine environments, although it can be deposited in marginal marine environments in special situations. The presence of peat has been critical in stratigraphical modelling undertaken in this research (Section 8.3.2).

3.10.4 Holocene alluvium and dune sands

Units coded **Q1a**, **Q1l**, **Q1f**, **Q1ds**, **Q1dm** in Table 3-1 and Figure 3-2.

Various types of Holocene age sediment occur in the LMC, including alluvium (**Q1a**), dune sands (**Q1ds** and **Q1dm**), fan (**Q1f**) and landslide (**Q1l**) sediments.

Holocene alluvial deposits (**Q1a**) consist of loose, well-sorted, sub-rounded, sub-spherical alluvial gravel with some sand, silt and clay with local peat. They are found in river valleys and modern floodplains. According to Begg *et al.* (2005), degradational gravel surfaces that are of low elevation and are not overlain by loess units can be considered Holocene in age (Q1a).

Holocene alluvium is extremely permeable due to grainsize, sorting, roundness, sphericity and lack of cementation and, from a groundwater perspective, is very productive, having high specific yield. Nevertheless, normally these deposits are not thick, limiting their potential as a water resource, particularly when associated rivers and streams are dry. Generally, groundwater in Holocene sediments in the LMC is present under unconfined hydraulic conditions. Wells in Holocene alluvium are commonly considered riparian as they either draw water from associated surface water systems or intercept groundwater that would otherwise have flown into them. Holocene gravel constitutes the main medium through which groundwater and surface water interact in the LMC area.

Holocene windblown loose sand in active unvegetated or sparsely vegetated dune fields and deflation zones (**Q1dm**) and windblown inactive dunes and associated facies (**Q1ds**) are porous and permeable, so they can store and transmit water. Dune sands are mapped in the lower part of the LMC, extending between Carnarvon

and Foxton Beach on the true right of the Manawatu River and Moutoa Floodway (Figure 3-2). They are also mapped at the southwestern most corner of the LMC on the Tasman Sea coastal area. The sand dunes can reach up to 30 m in elevation and they often embrace inter-dune swamps. Dune morphology varies from longitudinal dunes, barchan-style dunes to shore-parallel mounds, their shape probably influenced by topography and consequently, wind velocity.

Sand has good to moderate permeability and specific yield (e.g. Bear, 1972; Fetter, 2013; Freeze & Cherry, 1979). So, groundwater receives recharge and can be found in sand dune areas. Inter-dune swamps are indeed an outcrop of groundwater in sand covered areas in the LMC.

Holocene fan deposits (**Q1f**) are mapped only in a small area in the Pohangina Valley, near Awahou. These alluvial, colluvial and scree fan deposits consist of poorly sorted, poorly consolidated angular to sub-rounded boulders, cobbles, pebbles, gravel, sand and clay. They are not important from a hydrogeological point of view mainly due to their limited extent. Holocene earthflow hill slope deposits (**Q1l**) consist of poorly sorted clasts up to boulder size in a clay matrix. They are found in the LMC exclusively in areas classified as steep lowland (Figure 3-2 and Figure 3-11d). Their geomorphological setting and lithological properties make them unsuitable for storing and transmitting groundwater.

3.11 Interplay between alluvial deposition and sea level change

Wanganui Basin sediments are exclusively Pliocene and Quaternary in age, during which the region was characterised by dynamic interplay between sea level, tectonics, erosion and deposition. During the early stages of that period, the Wanganui Basin was a shelfal, subsiding depocentre. Then, it has been everted in the late part of that period and the present land has emerged from the influence of the sea (Begg *et al.*, 2005; Feldmeyer *et al.*, 1943; Fleming, 1953; Kamp *et al.*, 2004). Ongoing regional tectonic uplift is evidenced by the sequence of stranded marine benches. The Quaternary also witnessed smaller scale deformation, well-illustrated by the development of local folds and faults such as those at Mt Stewart-

Halcombe, Feilding and the Pohangina (Feldmeyer *et al.*, 1943; Fleming, 1953; Jackson *et al.*, 1998; Melhuish *et al.*, 1996). While regional-scale tectonic warping influenced the broader relative elevation of land and sea, local-scale tectonic features (faults and folds) progressively restricted the routes of the major rivers from the hinterland to the sea, particularly in the LMC. Subsequently, the Oroua and Pohangina rivers have broadly occupied the same courses throughout the Haweran until today, i.e. for the last 340 ka.

During the Pliocene and Quaternary, sea level has fluctuated on a cyclical basis, more recently by almost 125 m. This is particularly well documented for the last c. 1.8 Ma (Carter & Naish, 1998a; Imbrie *et al.*, 1984; Milankovitch, 1920). Cyclical sea level change has resulted in cyclicity in the deposition style in the Wanganui Basin, particularly in shallow marine environments. Interfingering non-marine beds and marine strata in the Maxwell Formation (late Nukumaruan age) is almost certainly due to sea level fluctuation.

As the Wanganui Basin landscape emerged from the sea during the Pliocene and Pleistocene, the shorelines were benched by marginal marine processes during high sea level stands. The elevated sea level during these periods resulted in lower river gradients behind the shorelines, changing the style of deposition to low energy, dominated by silt and sand. When the sea retreated from these high stands, rivers flowed across the marine benches to the sea, far beyond the present-day coastline, carrying gravel much further down their courses due to steeper gradients in this part of their catchments. Loess deposition was common during cold climatic conditions, because vegetation was reduced, and sediment supply increased (e.g. by frost heave, increased wind exposure, exposure of the plains between the high sea level coast and the low sea stand coast).

Analysis of lithological log data can help us define the paleogeographical changes related to sea level fluctuation and understand their likely impact on the deposits beneath the plains. For example, it can be assumed that the aggradational gravel units mapped at the surface as sequences of prominent terraces are likely to extend

down valley beneath the Holocene floodplain material. Begg *et al.* (2005) suggest that the gradient of the surface upslope from where the aggradational gravels disappear beneath Holocene alluvium can be extrapolated downslope to constrain the depth of burial of that surface.

The relative elevation of terraces is determined by the interplay between tectonic uplift and fluvial incision and deposition. The average rate of uplift and incision (r_x) can be calculated as follows:

$$r_x = \frac{h_x}{t_x} \qquad 3\text{-}1$$

where h_x is the height of the terrace and t_x is its age (Figure 3-18).

3.12 Geological history

The above geological data is synthesised to provide a geological history for the LMC and vicinity. Good appreciation of the area's geological history is instrumental for stratigraphical and hydrogeological conceptualisation.

During the Late Paleozoic to Early Cretaceous time, sand and mud forming the Torlesse Composite Terrane were deposited in deep marine basins along the eastern margin of Gondwanaland in a compressional or transpressional setting (Bradshaw, 1989). Active deformation of these strata (commonly involving bedding plane shear) commenced soon after they were deposited and continued until near the end of the Early Cretaceous. A major, abrupt tectonic event marks the termination of deep marine deposition around the Early Cretaceous, with significant and widespread tilting, folding and faulting. This period of intense deformation continued probably to the start of the Late Cretaceous. It marks the cessation (or near-cessation) of Mesozoic active margin compressional tectonics. It resulted in significant change in rock hardness, metamorphism and structural complexity. Begg and Johnston (2000) suggest that this event reflects the amalgamation of the various terranes of the Torlesse Composite Terrane when the Rakaia Terrane, the component of the Torlesse Composite Terrane that underlies the Tararua and Ruahine ranges, was amalgamated with terranes to the east, the Pahau and

Waioeka terranes. Begg *et al.* (2005) believe that the amalgamation event was probably the origin of at least some of the melange units found throughout the Torlesse Composite Terrane, including Esk Head Terrane.

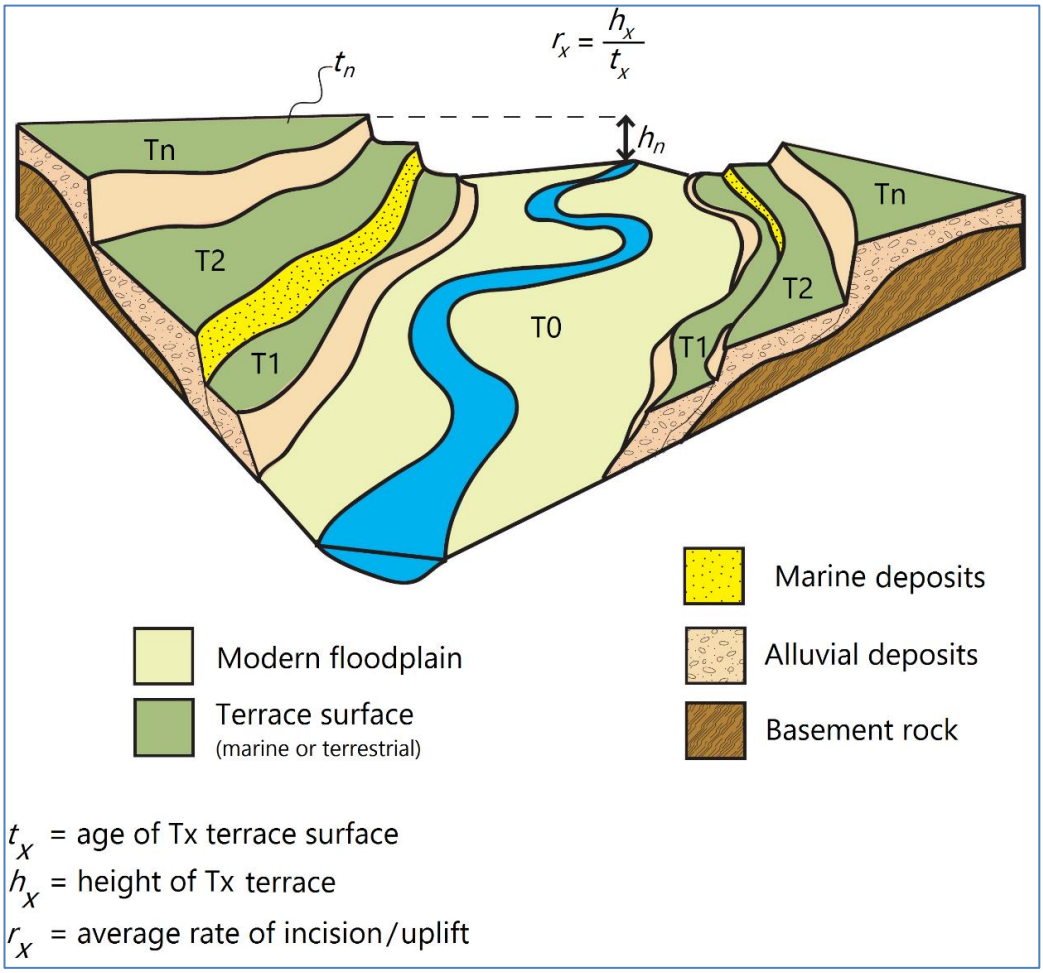

Figure 3-18. Method to calculate incision/uplift rates in deformed, terraced areas.

In the Wanganui Basin, the Paparangi Group (c. 3 Ma) lies uncomfortably on basement rock (Figure 3-19). This huge gap in the chronostratigraphical record reflects a long period of quiescence at the plate boundary extending from the cessation of transpressional activity at the plate boundary about 100 Ma ago until the inception of the Kaikoura Orogeny at the end of the Oligocene and Early Miocene (c. 25-20 Ma BP). This quiet period marks the opening of the Tasman Sea and the disintegration of the great Gondwanaland supercontinent. The transpressional activity that commenced at the start of the Kaikoura Orogeny at the plate boundary is continuing to the present day. Any deposition during that period

would subsequently have been eroded during the active period of the Kaikoura Orogeny. Hence, the earliest deposits found are 3 Ma, while the Kaikoura Orogeny started c. 25 Ma BP.

Possibly due to the mantle-driven crustal downwarping associated with renewed subduction at the plate margin 18 Ma ago, a marine basin developed in the Taranaki-Wanganui area (e.g. Kamp *et al.*, 2004). It was the locus of thick deposition, mostly siltstone and mudstone with minor sandstone interbeds, until it emerged from the sea within the last 700 ka (Begg *et al.*, 2005). Gradually, the centre of the basin migrated from the northwest to the southeast, again, possibly reflecting the onset and migration of subduction at the plate margin. South-eastward migration of the depocentre resulted in onlap of the basinal sequence to basement rocks at a progressively younger age from northwest to southeast. Deposition in the basin commenced in earnest in the Rangitikei area about 4-5 Ma ago. Basin eversion followed the migration of the depocentre, so the south-eastern part of the basin was last to emerge. Basinal deposits in the Manawatu and Horowhenua area represent the final gasp of onshore Wanganui Basin deposition (Begg *et al.*, 2005).

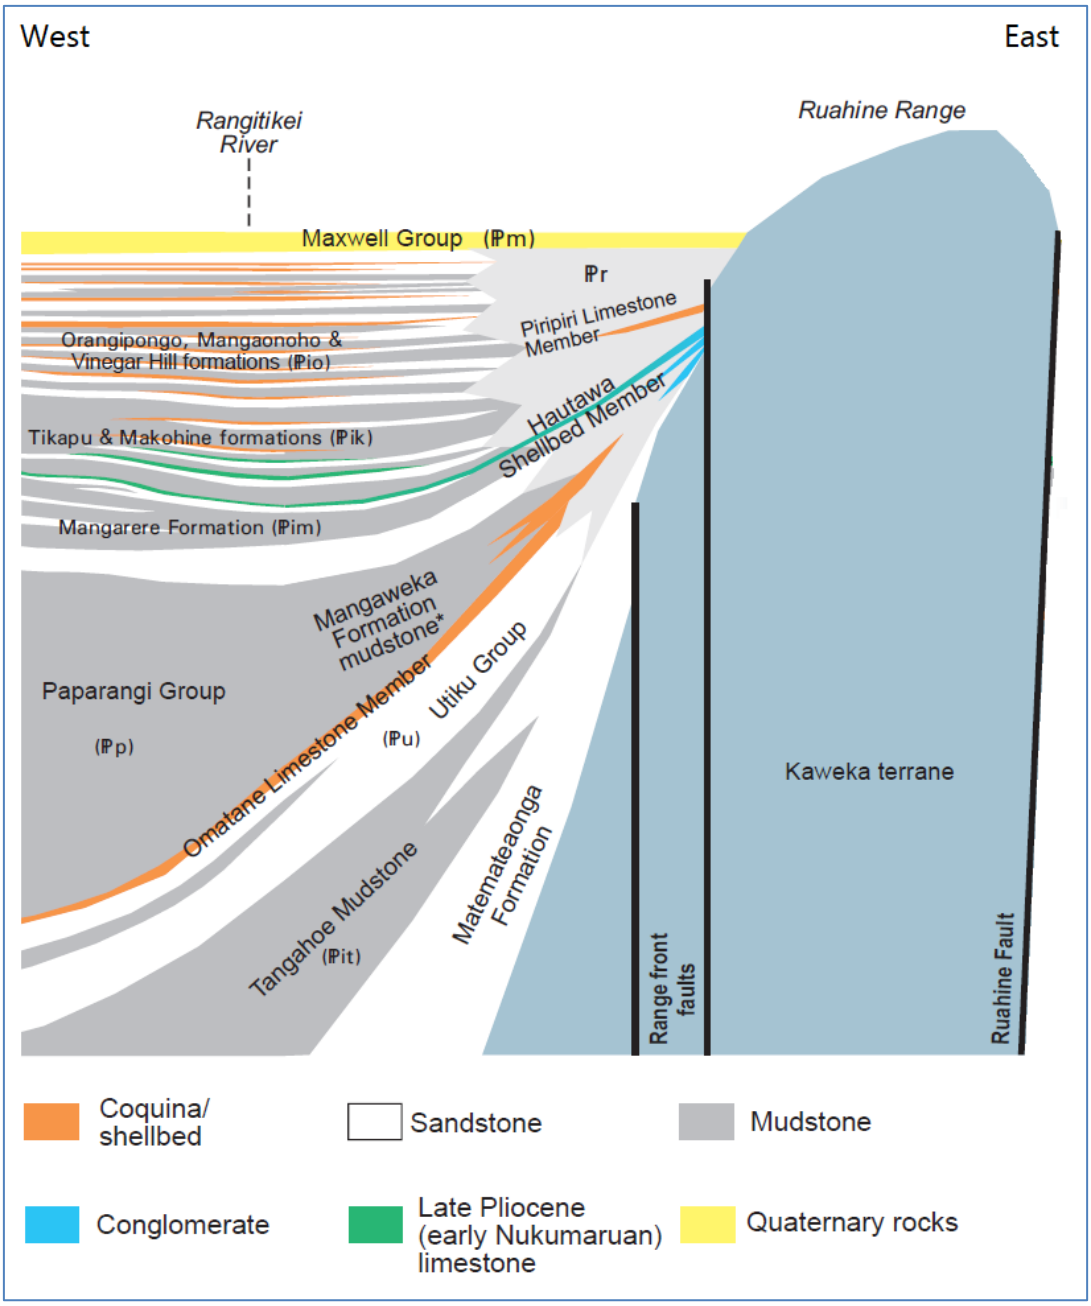

Figure 3-19. Schematic cross-section showing the relation between the Plio-Pleistocene sequence and basement rocks in the Wanganui Basin (after Lee *et al.*, 2011).

The LMC emerged from the sea before the start of the active reverse and strike-slip faulting on the large regional faults of the present day (e.g. the Wellington and Northern Ohariu faults), and also the faults and their associated folds of the Manawatu area. Commencement of uplift of the Tararua and Ruahine ranges was associated with the initiation of displacement on the Wellington Fault c. 1-1.5 Ma BP, and it seems likely that the Northern Ohariu Fault developed at

about the same time (Begg *et al.*, 2005). Uplift of the ranges and hills resulted in a large and increasing supply of greywacke cobbles from the developing catchment systems. There must have been a significant river system flowing from the northern and eastern hinterland to the residual Wanganui Basin prior to the commencement of uplift of the Tararua and Ruahine ranges to account for subsequent development of the Manawatu Gorge. The catchment size and volume of the water provided the power needed to incise into the growing range at a rate that could keep pace with its development. Quaternary age fluvial sediments sourced from the ranges were deposited in valleys and on the plains. Slow uplift and deformation have raised flights of marine and river terraces. Windblown river silt was deposited as loess on older deposits, particularly on older terraces and slopes. The Oroua and Pohangina catchments developed through the uplifted and tilted deposits of the Wanganui Basin, deeply dissecting the sediments through which their rivers flow. Evidence suggests that, at least in the east, stream capture is continuing.

Except for the remnant of the erosion surface above the Manawatu Gorge, the entire landscape of the region post-dates uplift from the sea <1-1.5 Ma BP. Younger Quaternary sequences have been deformed progressively by the processes associated with basinal uplift and active faulting since deposition (Begg *et al.*, 2005).

3.13 Soil

Although soil is merely a thin skin covering the land, it plays a very important role in the hydrological cycle. Largely, its physical and biological properties and moisture content determines the proportions of natural precipitation and irrigation waters that turn to evapotranspiration, surface runoff or groundwater recharge. Soils physical composition and properties also influence groundwater quality, directly and indirectly. Therefore, it needs to be included in this study.

Floodplain land in the LMC is amongst the most fertile areas in the south-western North Island of New Zealand. It forms a triangle of about 1,000 km² of low-lying land that extends between the northern Horowhenua around Levin in the south to

Marton in the north, to the Manawatu Gorge inland. Soils in this area are generally productive, and their fertility can be further enhanced with irrigation and fertilising (Zarour, 2008). Soil Orders and Groups in the LMC are mapped in Figure 3-20 and Figure 3-21, respectively using Fundamental Soil Layers (FSLs) digital data by Landcare Research (Hewitt, 2010). Table 3-6 summarises LMC soil properties based on the New Zealand Soil Classification (NZSC).

The LMC is covered by sandy soils and swampy hollows around the coast with river flats and loess-covered terraces farther inland. River flats and swamp areas contain fertile alluvial and organic soils (Recent and Gley soils, respectively). The floodplains also contain areas covered by Organic Soils. Areas covered by Gley and Recent soils have low surface water drainage network density reflecting their high permeability (Figure 3-15 and Figure 3-21). Brown soils covering sand dunes have lower permeability and, consequently, higher surface water drainage network density. The flat fertile soils suit intensive cropping, dairy and sheep farming while the hill country favours only sheep and beef farming. The characteristic pale straw (yellow-grey) coloured subsoils of Pallic Soils predominate on the drier terraces inland. These soils have hard, brittle fragipans that form where annual rainfall is between 500 and 1,000 mm. Multiple loess sheets cover these terraces (Table 3-7), greatly reducing their infiltration capacity (Table 3-8). Fragipan in loessial soils severely restricts land-surface recharge and the depth of plant rooting (Poulsen, 2013).

Pallic Soils are normally dry for part of the growing season, especially summer to mid-autumn and have limited uses (mostly sheep grazing) because the subsoil is dense. Roots cannot penetrate to deeply buried moisture, so the soil becomes even drier. Some younger Pallic soils are not so dense and have a range of agricultural uses. Although dry in summer, the soil can be wet in winter or spring. When saturated, they instigate high rates of surface runoff.

Brown Soils cover 43.65% of LMC area, nearly the same proportion as the national coverage. They occur in places where summer drought is uncommon and that are

not waterlogged in winter. They are found mainly in elevated rugged areas in the LMC (Figure 3-14 and Figure 3-20), which normally receive more than 1,000 mm of precipitation per year. These soils are often well drained (Houlbrooke & Monaghan, 2009).

Areas close to the volcanic plateau consist largely of Allophanic Soils, which lack some essential trace elements.

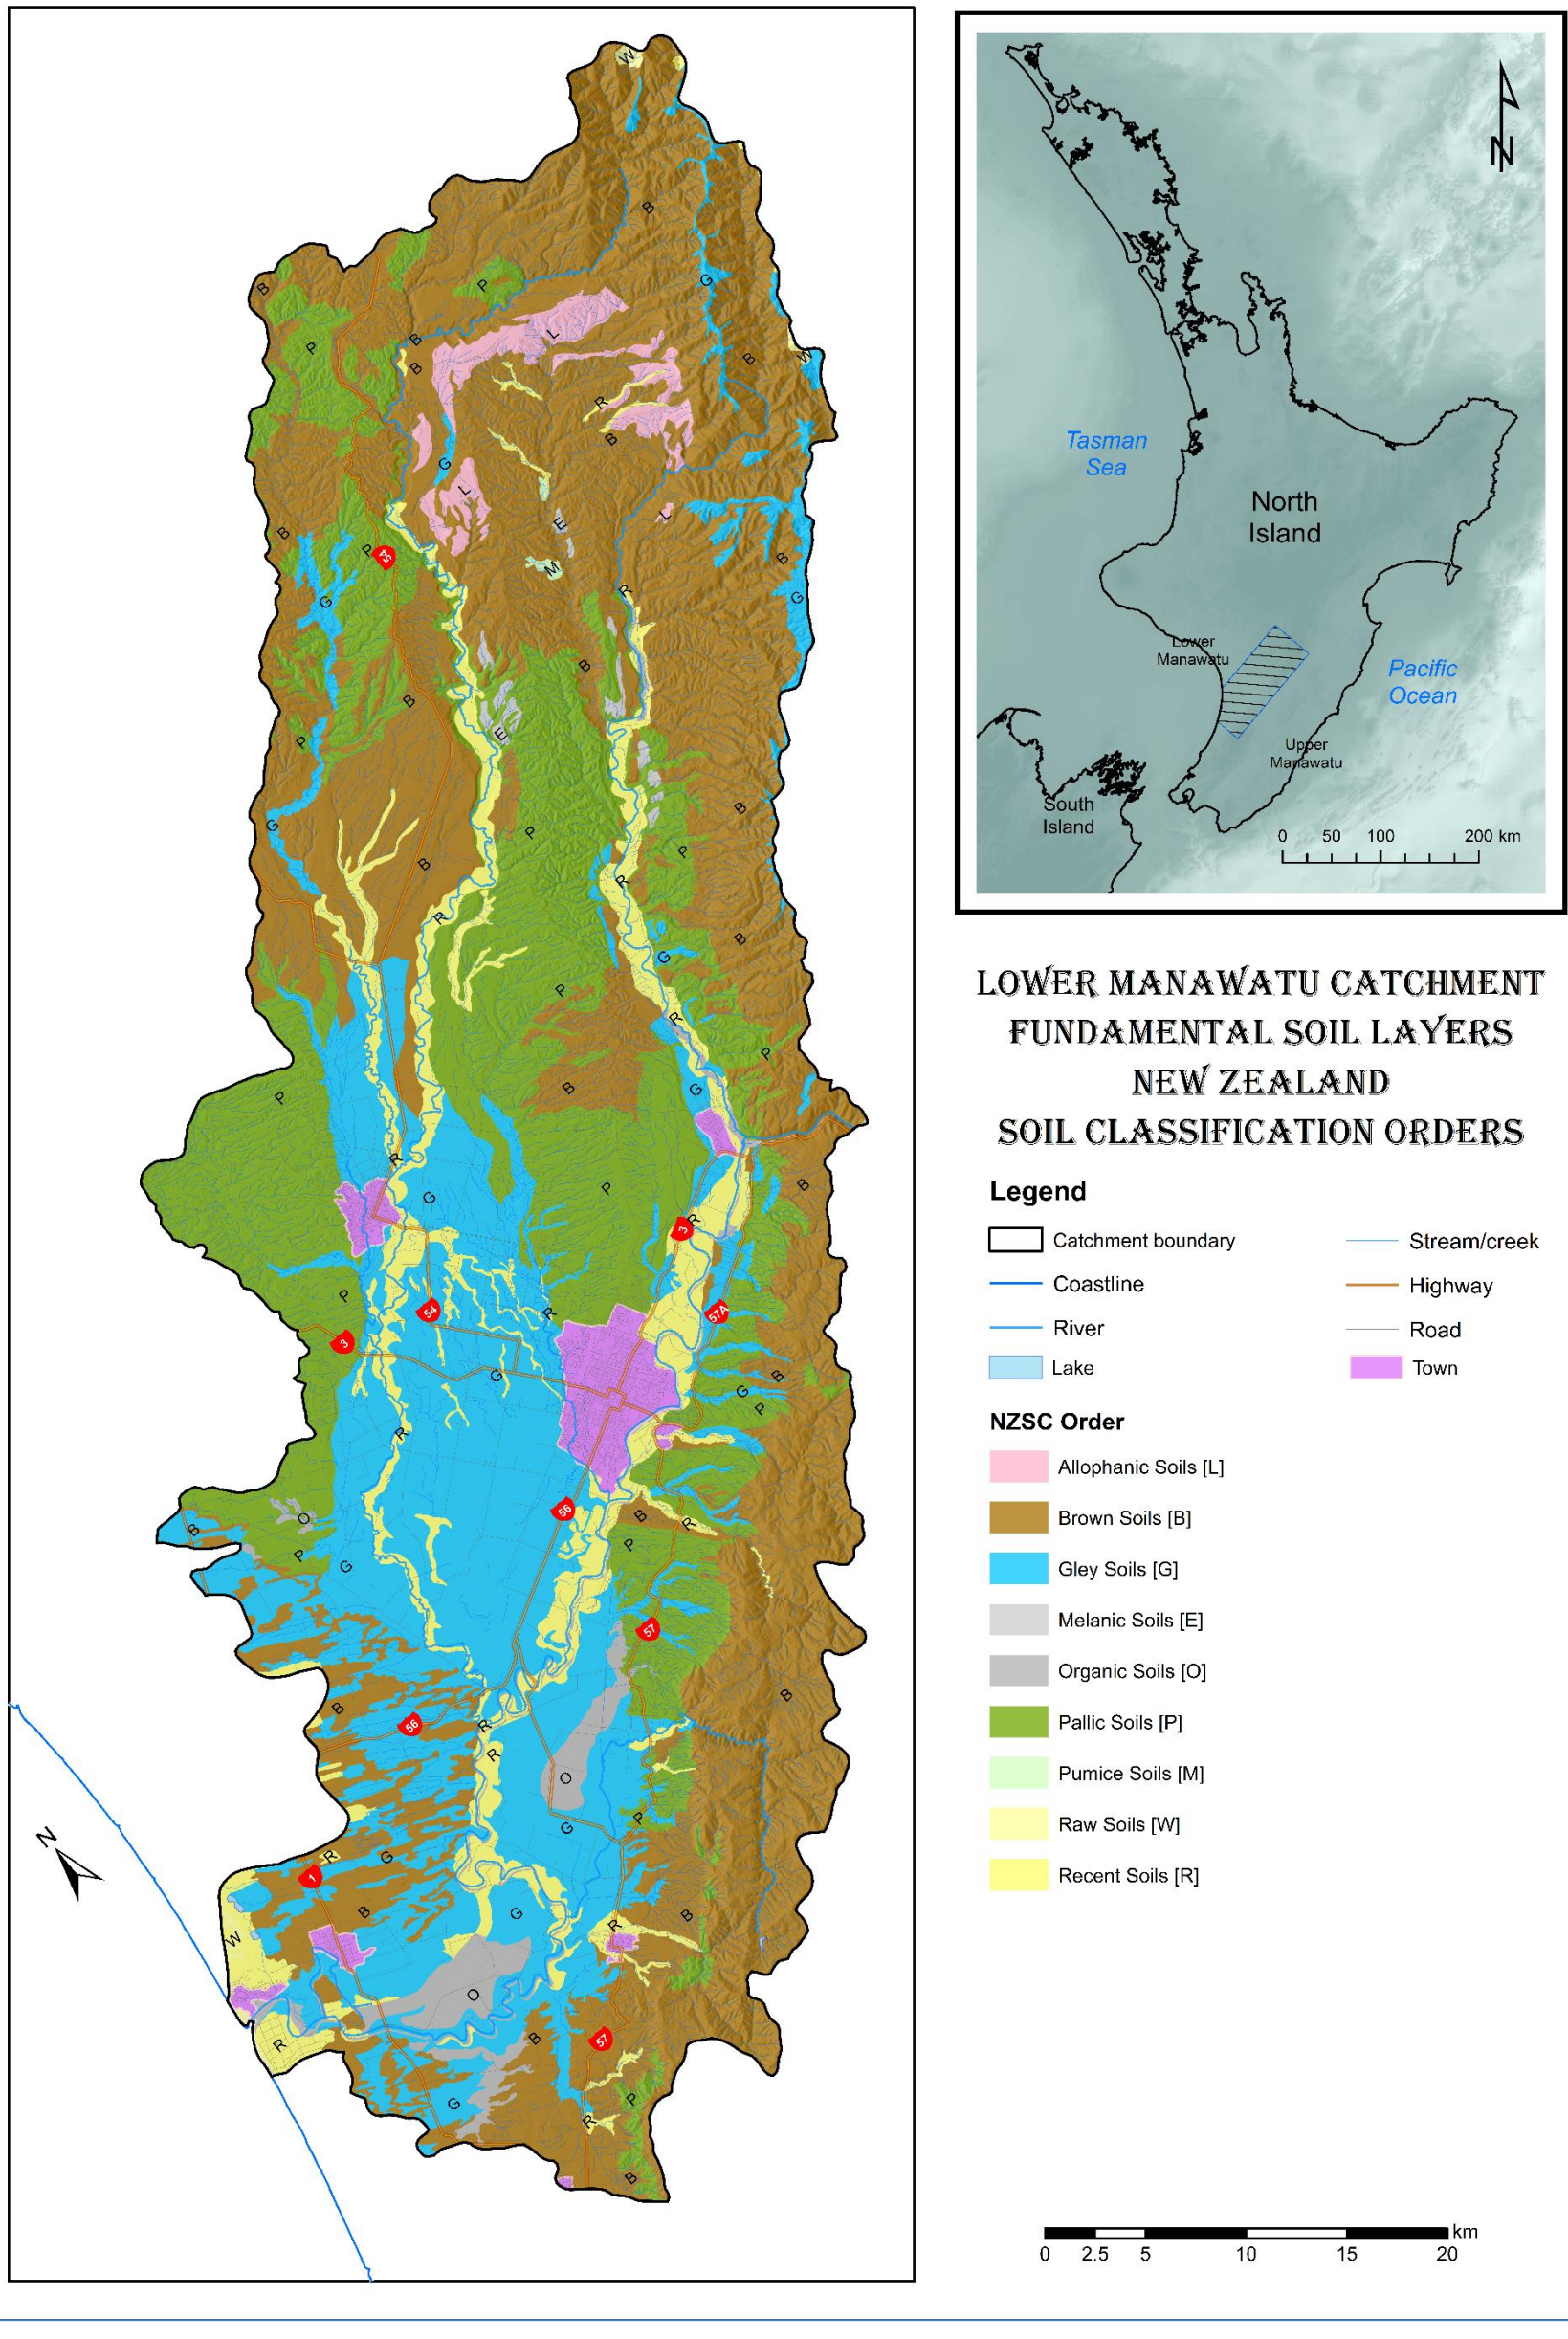

Figure 3-20. Soil classification orders in the LMC drawn using Fundamental Soil Layers (FSLs) digital data by Landcare Research (Hewitt, 2010).

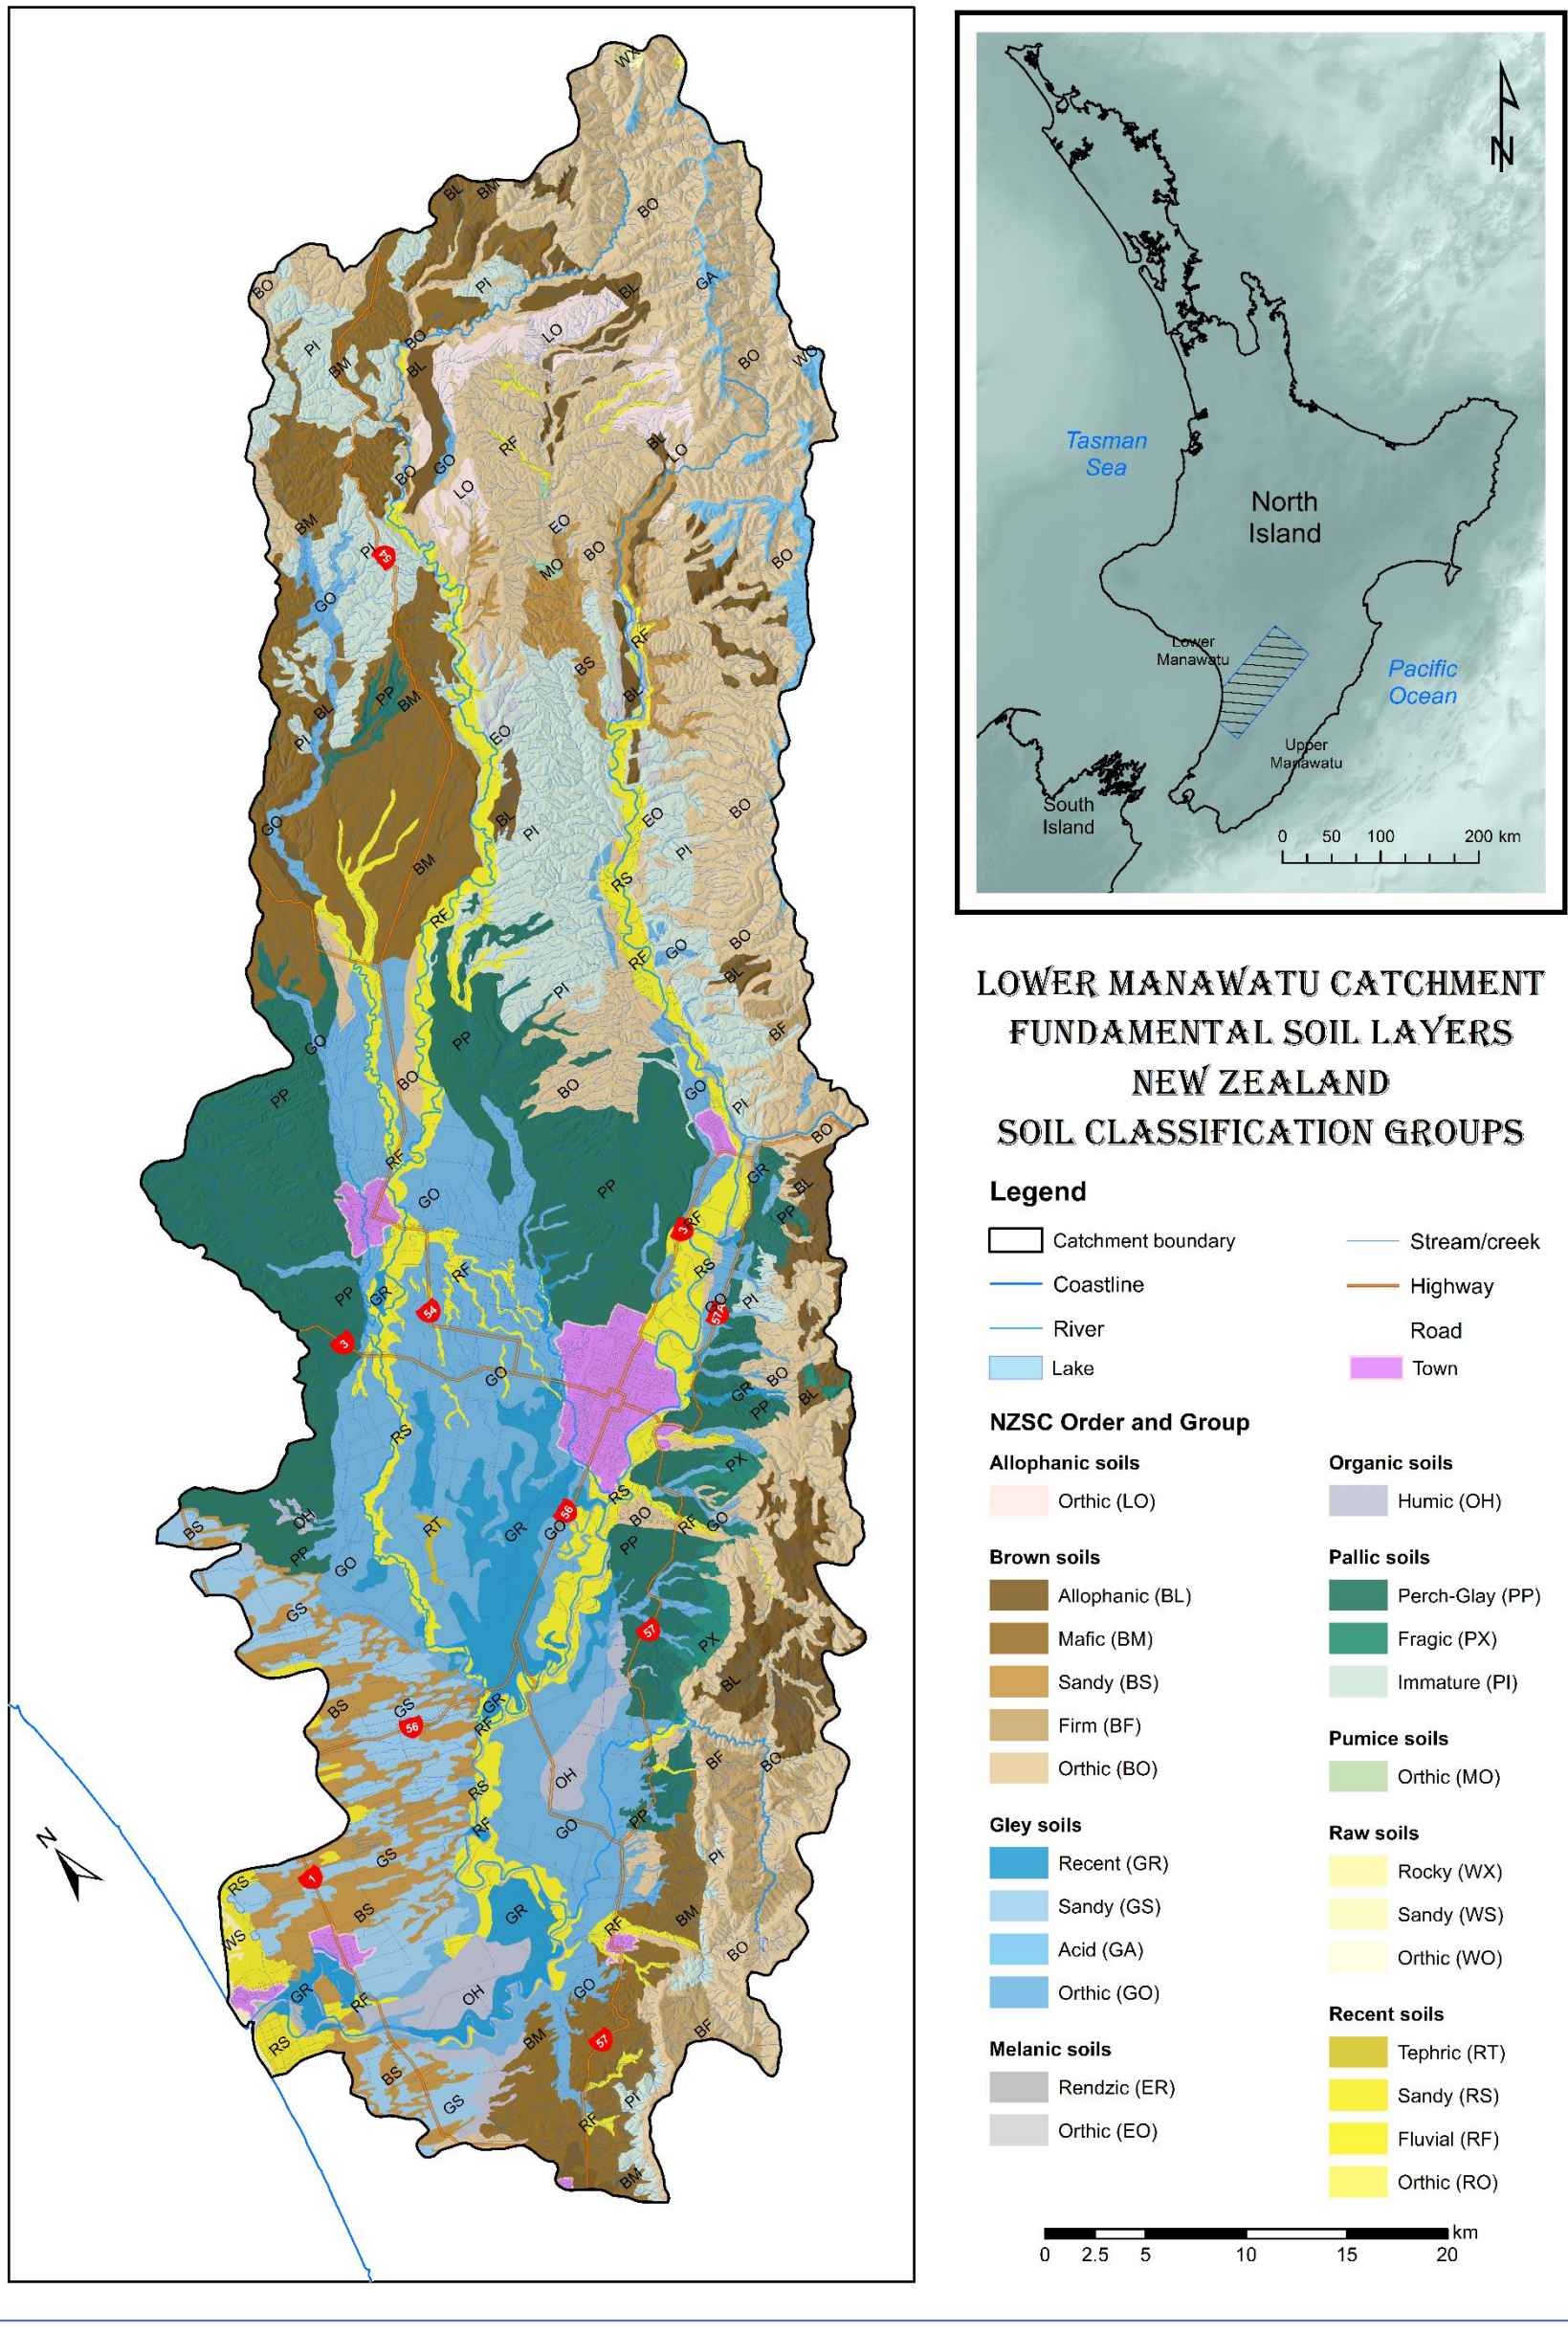

Figure 3-21. Soil classification groups in the LMC drawn using Fundamental Soil Layers (FSLs) digital data by Landcare Research (Hewitt, 2010).

Table 3-6. Soil Orders and Groups in the LMC.

Soil Order	General description	Characteristics	Soil Groups in LMC
Allophanic Soils [L] 37.45 km^2 1.40% of LMC area	Occur predominantly in the North Island volcanic ash, and in the weathering products of other volcanic rocks. Dominated by allophane with imogolite or ferrihydrite. These stiff, jelly-like minerals coat the sand and silt grains and maintain porous, low density structure with weak strength. Identified by a distinctly greasy feel when moistened and rubbed firmly between the fingers. Easy to dig and samples crumble easily when crushed in the hand.	Little resistance to root growth due to low bulk density. Topsoils are stable and resist the impact of machinery or grazing animals in wet weather. Erosion rates are generally low except on steep slopes or exposed sites. Low natural fertility. The ability to retain phosphorous is high – up to 30 tonnes/ha of phosphorous may be locked away in intensively farmed topsoils. Contain large populations of soil organisms, particularly in A horizons.	**Orthic Allophanic [LO]**: other Allophanic Soils.
Brown Soils [B] 1,169.10 km^2 43.65% of LMC area	New Zealand's most extensive soils, covering 43% of the country. Occur in places where summer drought is uncommon and that are not waterlogged in winter. Have a brown or yellow-brown subsoil below a dark grey-brown topsoil. The brown colour is caused by thin coatings of iron oxides weathered from the parent material.	Relatively stable topsoils with well-developed polyhedral or spheroidal structure. Have low to moderate base saturation. Clay minerals are dominantly mica/illite and vermiculite, with allophane in Allophanic Brown Soils. Contain large, active populations of soil organisms, particularly earthworms.	**Allophanic Brown [BL]**: have a horizon with soil properties dominated by allophanic material. **Mafic Brown [BM]**: in materials from dark igneous rocks or sediments. **Sandy Brown [BS]**: dominated by sand or loamy sand to depth. **Firm Brown [BF]**: strong, apedal subsurface horizon. **Orthic Brown [BO]**: other Brown Soils.
Gley Soils [G] 560.86 km^2 20.94% of LMC area	Occur in low parts of the landscape where the water table is high or where there are seepages. Together with Organic Soils, they represent the original extent of New Zealand wetlands, which have been greatly restricted in area by artificially drainage to form productive agricultural land. Gley Soils are strongly affected by waterlogging and have been chemically reduced. They have light grey subsoils, usually with reddish brown or brown mottles. The grey colours usually extend to more than 90 cm depth. Waterlogging occurs in winter and spring, and some soils remain wet all year.	These soils have high water tables, shallow potential rooting depth and relatively high bulk density. Trafficability is limited when soils are wet. Drainage is necessary for most agricultural development. Have common segregated iron and manganese oxide mottles, concretions or nodules. Organic matter content is usually high. Many soil organisms are restricted because of anaerobic conditions.	**Recent Gley [GR]**: on young land surfaces, mainly alluvial or estuarine. **Sandy Gley [GS]**: dominated by sand or loamy sand to depth. **Acid Gley [GA]**: strongly or extremely acid. **Orthic Gley [GO]**: other Grey Soils.
Melanic Soils [E] 7.43 km^2 0.28 % of LMC area	Occupy scattered small areas, associated with lime-rich rocks or dark (basic) volcanic rocks. Arguably the most naturally fertile soils in New Zealand. They grow high quality pinot noir. Characterised by well-structured black or dark grey topsoils. The subsoil either contains lime, or has well-developed structure and is neutral or only slightly acid.	Topsoil structure is usually stable. The soils shrink on drying and swell on wetting. High natural fertility. High base saturation with high exchangeable calcium or magnesium. The clay fraction is usually dominated by swelling (smectite) clays. Biologically very active with high populations of soil organisms.	**Rendzic Melanic [ER]**: limestone or lime rich rock at shallow depth. **Orthic Melanic [EO]**: other Melanic Soils.

Soil Order	General description	Characteristics	Soil Groups in LMC
Organic Soils [O] 39.36 km^2 1.47% of LMC area	Occur in wetlands or under forests that produce acid litter in areas with high precipitation. They are formed in the partly decomposed remains of wetland plants (peat) or forest litter. Some mineral material may be present but the soil is dominated by organic matter. They serving as giant sponges in the landscape with the ability to hold up to 20 times their weight in water.	Very low bulk densities, low bearing strength, high shrinkage potential when dried, very low thermal conductivity and high total available-water capacity. High cation exchange capacities. Usually strongly or extremely acidic and nutrient deficiencies are common. High carbon/nitrogen ratios indicate slow decomposition rates. Many soil organisms are restricted because of anaerobic conditions.	**Humic Organic [OH]**: in peat that is strongly decomposed.
Pallic Soils [P] 587.82 km^2 21.95% of LMC area	Predominantly occur in the seasonally dry eastern part of the North and South Islands and in the Manawatu where annual precipitation usually between 500 and 1,000 mm and the climate is typically droughty in summer and moist or wet in winter. Parent materials are commonly loess derived from greywacke. Have pale coloured subsoils, due to low contents of iron oxides. Weak structure and high density in subsurface horizons. Dry in summer and wet in winter.	Slow permeability with limited rooting depth, and medium to high bulk density. A cubic metre of some subsoils can weigh more than 1.8 tonnes. They are susceptible to erosion because of high potential for slaking and dispersion. Medium to high nutrient content (except for sulphur), high base saturation, low concentrations of secondary oxides, and low organic matter contents. Strongly worm-mixed, at the boundary of the A and B horizons.	**Perch-Gley Pallic [PP]**: periodic wetness caused by a perched water table. **Fragic Pallic [PX]**: a compact pan in the subsoil. **Immature Pallic [PI]**: weakly expressed pallic soil features.
Pumice Soils [M] 1.55 km^2 0.06% of LMC area	Predominantly occur in the central North Island, particularly in the Volcanic Plateau. Mostly derived from one of the greatest volcanic eruptions ever known from the crater now occupied by Lake Taupo. Sandy or gravelly soils dominated by pumice, or pumice sand with high content of natural glass. Drainage of excess water is rapid but the soils are capable of storing large amounts of water for plants. They occur in tephras ranging from 700 to 3,500 years old.	Low clay contents, generally less than 10%. Low soil strengths, especially when disturbed. High macroporosity and deep rooting depth. Fresh or only moderately weathered pumice with low reserves of major nutrient elements. Trace elements are likely to be deficient. Clay minerals are dominated by allophane. Soil animal populations are low with most species concentrated in the topsoil. Earthworm populations are limited by droughtiness and coarse texture.	**Orthic Pumice [MO]**: other Pumice Soils.

Soil Order	General description	Characteristics	Soil Groups in LMC
Raw Soils [W] 4.10 km^2 0.15% of LMC area	Raw Soils are scattered throughout New Zealand, particularly in association with high mountains (alpine rock areas and active screes), braided rivers, beaches and tidal estuaries. They cover 3% of New Zealand. Infant soils that may never grow older because of active erosion or sedimentation. Raw Soils are very young soils. They lack distinct topsoil development or are fluid at a shallow depth. They occur in environments where the development of topsoils is prevented by rockiness, by active erosion, or deposition.	PHYSICAL PROPERTIES: Raw Soils have no B horizon, and a topsoil is either absent or less than 5 cm thick. Most occur in environments with active erosion or deposition. Fluid soils have a continuously high water-table. CHEMICAL PROPERTIES: Fertility is limited by lack of organic matter and nitrogen deficiency. BIOLOGICAL PROPERTIES: Vegetation cover is sparse and often consists of ephemeral herbaceous plants, mosses, or lichens.	**Rocky Raw [WX]**: rock at shallow depths. **Sandy Raw [WS]**: dominated by sand or loamy sand to depth. **Orthic Raw [WO]**: other Raw Soils.
Recent Soils [R] 201.83 km^2 7.54% of LMC area	Occur on young land surfaces, including alluvial floodplains, unstable steep slopes and slopes mantled by young volcanic ash. Age varies depending on the environment and soil materials, but most are less than 1,000 to 2,000 years old. Weakly developed, showing limited signs of soil-forming processes. A distinct topsoil is present but a B horizon is either absent or only weakly expressed.	Variable texture, with common stratification of contrasting materials and high spatial variability. Generally deep rooting and high plant-available water capacity. Natural fertility is usually high with high base saturation. Clay mineralogy usually dominated by illite. Normally well-established continuous cover of vascular plants.	**Tephric Recent [RT]**: in sediments originating as volcanic ejecta. **Sandy Recent [RS]**: dominated by sand or loamy sand to depth. **Fluvial Recent [RF]**: in sediments deposited by flowing water. **Orthic Recent [RO]**: other Recent Soils.

Table 3-7. Quaternary terraces ages, names and loess cover in the LMC (after Begg *et al.*, 2005).

OIS	Relative age	Absolute age (ka)	Terrace name	Number of loess sheets
1	Holocene	0–12	Unnamed	–
2	Late Otiran Glacial	12–25	Ohakea	–
3	Middle Otiran Glacial	25–60	Rata	1
4	Early Otiran Glacial	60–71	Porewa	2
5	Kaihinu Interglacial	71–128	Tokomaru	3
6	Waimea Glacial	128–186	Greatford / Marton	3
8	Waimaunga Glacial	245–303	Burnand	4
9	Brunswick / Braemore Interglacial	303–339	Brunswick / Braemore	5

11	Ararata / Rangitatau Interglacial	362–423	Ararata / Rangitatau	6
13	Ball Interglacial	478–524	Ball	7
15	Piri Interglacial	565–620	Piri	8

Table 3-8. General order of magnitude for saturated hydraulic conductivity for soil horizons in loessial soils (after Poulsen, 2013).

Soil horizon	Saturated hydraulic conductivity (m/d)	
	infiltration tests	cores lab testing
A horizon	10^{0} –10^{-1}	
B horizon	10^{-1}–10^{-2}	10^{-4}–10^{-5}
Fragipan	10^{-3}–10^{-4}	10^{-5}–10^{-6}
Loess	similar to or slightly higher than fragipan	

Chapter 4 Climate, soil moisture and groundwater recharge

4.1 Introduction

Water enters the LMC only in the form of atmospheric precipitation and surface flow through the Manawatu Gorge. This chapter is aimed at the conceptualisation and quantification of groundwater recharge from precipitation and irrigation returns. As a by-product, the calculations produced estimates of soil moisture content, actual evapotranspiration, irrigation water demand and surface runoff. Groundwater interaction with surface water in the LMC is discussed in Chapter 5.

4.2 Pathway of precipitation water

Water reaching the ground surface in the form of precipitation and/or irrigation is proportioned according to Eq. 4-1. Figure 4-1 schematically shows this part of the hydrological cycle and subsurface hydrological zones.

$$P + IR = R_O + ET + DP + \Delta S \qquad 4\text{-}1$$

where P is precipitation, IR irrigation, R_O surface runoff, ET evapotranspiration, DP deep percolation and ΔS change in soil water storage. Deep percolation of soil water below the root zone forms groundwater recharge (RCH).

Eq. 4-1 and Figure 4-1 assume that DP water can freely drain from the soil profile into the underlying permeable geology to recharge groundwater. Where the underlying geology is impermeable, groundwater recharge is assumed not to be able to occur. In addition, it is assumed that there is no upward groundwater seepage into the soil zone, no preferential flow paths and no lateral soil water movement. Notwithstanding, rising water table has been noted in places in the LMC and there is potential for preferential and lateral soil moisture movement. However, these phenomena can generally be ignored in regional-scale hydrogeological assessments and models.

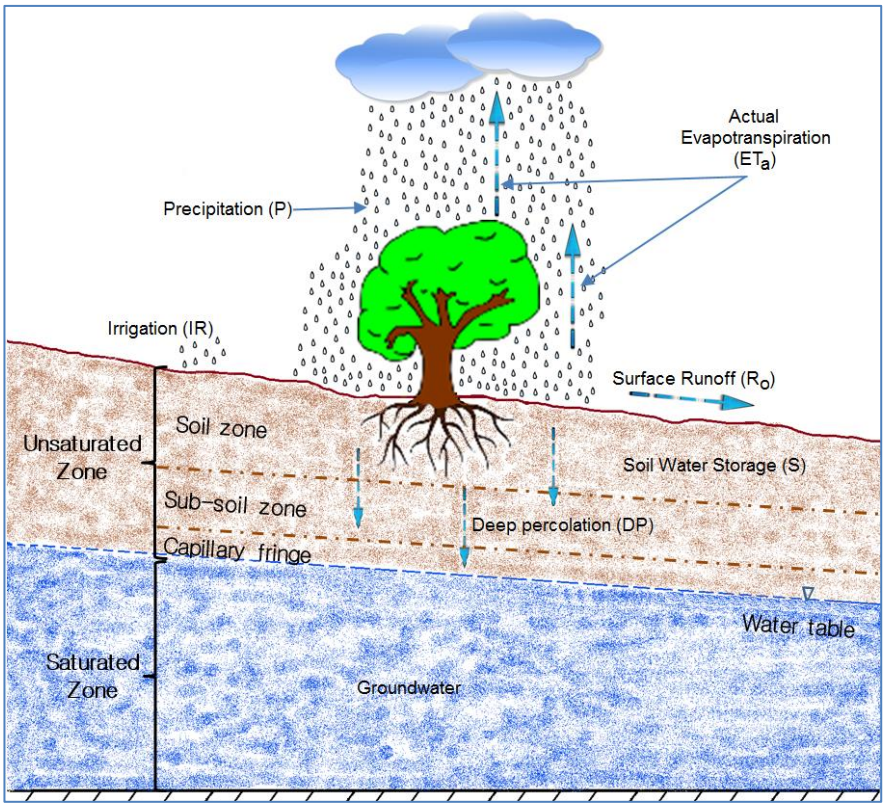

Figure 4-1. Schematic diagram showing the apportionment of precipitation and/or irrigation water reaching the ground surface.

According to Kim and Mohanty (2016), lateral moisture transfers are fairly marginal in regional-scale soil water budgets and, consequently, they are commonly ignored at the grid- and subgrid- scales, effectively resulting in modelling soil moisture exchanges as a 1D process. Hardie (2011) clarifies that preferential water flow in soil can take place due to the presence of: (1) continuous root channels, earthworm burrows, fissures or cracks within well-structured soils (macropores), (2) instabilities in the wetting front develop due to water repellence or air entrapment (unstable flow or fingering), (3) textural or lithographical boundaries resulting in lateral redirection or funnelling of infiltration via pathways of least resistance, bypassing the less permeable zones (funnel flow or heterogeneity-driven flow), (4) depression focused recharge, and (5) oscillatory flow. Preferential and lateral water flows in soil are ignored in this research as they occur at much finer scales than what can be analysed using the available low resolution soil and climate data (Sections 3.3.4 and 4.5, respectively) and their analysis requires much

higher resolution than that of the 500x500 m grid used in the numerical groundwater flow models (Section 8.5.2).

4.3 Soil moisture

4.3.1 Conditions and definitions

The fate of precipitation water depends on climate conditions, soil saturation level and land use and cover, including plant types, rooting depth and growth level. Figure 4-2 schematically shows various possible soil moisture scenarios and corresponding plant and hydrological conditions.

Figure 4-2. Possible soil moisture conditions, corresponding plant and hydrological conditions.

Terminology used in Figure 4-2 and soil sciences literature in general includes:

- Field Capacity (FC), also known as 'Full Point', is the level of moisture in the soil after excess water has drained away. This implies that above FC, deep percolation (groundwater recharge) can take place.
- Permanent Wilting Point (PWP) is the minimal level of soil moisture the plant requires not to wilt. Below this point, plants wilt and cease to grow.
- Stress Point (SP), also known as 'Refill Point', is the soil moisture level at which plant roots cannot extract water at the rate they require, subjecting the plant to 'stress'. It occurs approximately half way between FC and PWP.
- Readily Available Water (RAW), otherwise known as 'Growth Water' and termed in New Zealand Profile Readily Available Water (PRAW), is soil water that is easily available for plants to use. It corresponds to the soil moisture range between FC and SP.
- Total Available Water (TAW), otherwise known as 'Survival Water' and termed in New Zealand Profile Available Water (PAW), is the soil moisture range between FC and PWP.
- Soil Moisture Deficit (SMD) is the amount of moisture required to return the soil moisture to FC.

Soil grain-size (texture) and particle arrangement (structure) play a vital role in determining soil hydraulic properties because soil TAW is determined by the capillary porosity. Soil stone, clay and organic matter content also affect its moisture storage ability. In addition, the amount of soil water available to plants depends on the depth of soil that roots can exploit (the root zone). The root zone for various plants is not the same. Figure 4-3 shows the relationship between soil texture and soil hydraulic properties.

4.3.2 Influence over evapotranspiration

Evapotranspiration is possible as long as the soil moisture content (SMC) is above the PWP level. When soil moisture drops below the SP level, evapotranspiration occurs at depleted rates. A dimensionless water stress coefficient (K_s) is defined to express evapotranspiration reduction depending on available soil water. Where SMC is at or above the SP level, K_s equals 1. It drops linearly from 1 to 0 between the SP and the PWP levels (Figure 4-4).

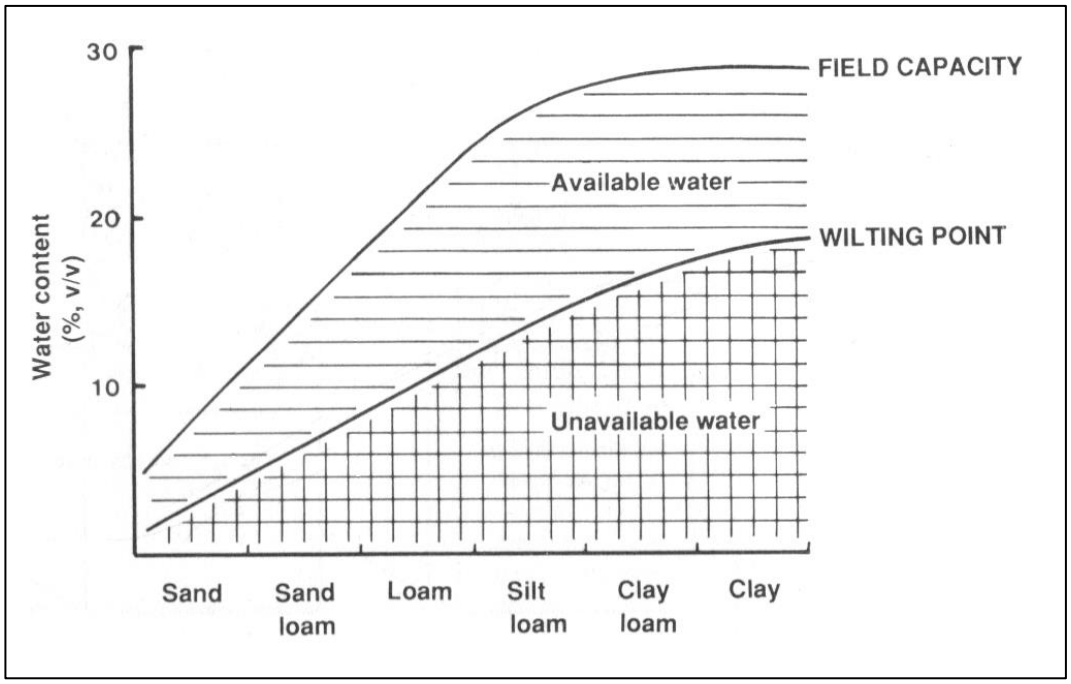

Figure 4-3. Schematic diagram showing relationship between soil texture, field capacity (FC), permanent wilting point (PWP) and total available water (TAW) (after McLaren & Cameron, 1996).

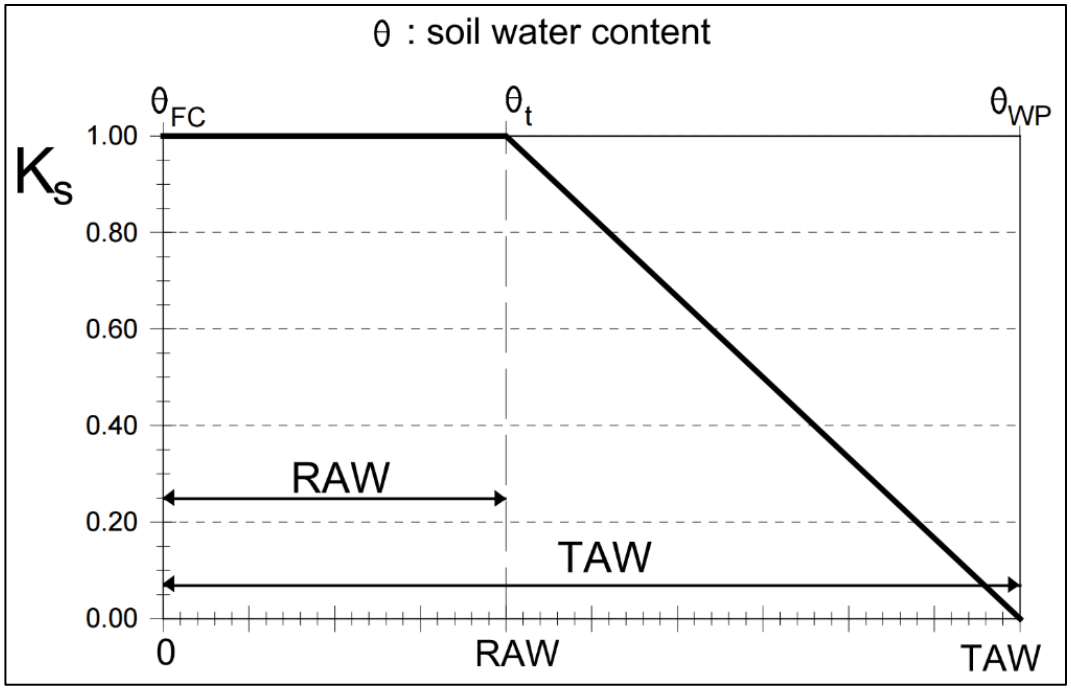

Figure 4-4. Water stress coefficient (K_s) under various soil moisture conditions (after Allen *et al.*, 1998).

4.3.3 Influence over surface water runoff

Surface runoff (R_O) is the portion of precipitation (rain and/or irrigation water) that appears as flowing water in the surface drainage network of a watershed during and following a rainfall event (Mekonnen *et al.*, 2016). It is determined by many factors including storm characteristics, antecedent SMC, watershed geography, soil physical properties (depth, thickness, texture, structure), land cover and land use. It only occurs when the water reaching the ground surface cannot infiltrate into the soil at a rate equal to or greater than rainfall intensity. Soil infiltration rate is controlled by three parameters:

(1) Soil texture – infiltration rate is higher for coarse textured soils than for fine textured soils

(2) Soil structure – water infiltrates faster in granular soils but very slowly into massive soils, especially clay-rich compact varieties

(3) Soil moisture content – water infiltration rate is higher when the soil is dry than when it is wet, except for hydrophobic soils (e.g. peat and sand).

Despite their importance, soil texture and structure will not be considered explicitly in this research as factors controlling surface runoff. They are implicitly included in soils hydraulic characteristics, namely FC and WP.

Figure 4-2 assumes that runoff can only take place when the soil is fully saturated. Precipitation on impervious surfaces like greywacke basement outcrops and sealed built-up areas will also turn into surface runoff after satisfying evapotranspiration demand. In general, surface runoff will take place where the intensity of effective rainfall[20] exceeds the soil infiltration capacity. Rainfall intensity data are not available for the LMC, so infiltration rates and storm characteristics have not been included in runoff estimations.

[20] Effective rainfall is rainfall less evapotranspiration.

4.3.4 Influence over groundwater recharge

Figure 4–2 assumes that deep drainage (groundwater recharge) occurs only when SMC exceeds soil FC. In reality, however, deep drainage can take place even when soil moisture content is below FC through bypass flow. This prospect is nearly impossible to specifically account for in regional–scale studies and is arguably more important in rocky aquifers than in unconsolidated aquifers like the system in the LMC. Hence, bypass groundwater recharge is disregarded in this thesis.

4.3.5 Modelling

Soil moisture balance (SMB) models utilise the concepts presented in Eq. 4–1, Figure 4–1 and Figure 4–2 to represent the soil component of the hydrological cycle for a variety of purposes, including calculating crop water demand and estimating catchment water yield. SMB modelling has been regularly utilised to calculate groundwater recharge (e.g. Bekesi & McConchie, 1999; de Silva & Rushton, 2007; Rushton, 2003; Rushton *et al.*, 2006; Scott, 2004; Wilson & Lu, 2011). For groundwater recharge calculations, Eq. 4–1 can be rewritten as follow:

$$RCH = P + IR - ET - R_O + \Delta S \qquad 4\text{–}2$$

Calculating groundwater recharge by SMB modelling requires knowledge on the soil moisture content (SMC) antecedent state, rain, potential evapotranspiration, land cover (including land use and crop type), soil hydraulic properties and irrigation practices. The soil water budget can be balanced at any term, e.g. daily, 10–daily, monthly, quarterly or yearly. The smaller the modelling time step the more 'accurate' the balance.

4.4 Potential and actual evapotranspiration

Water is lost from land and water surfaces to atmosphere through evaporation and transpiration, collectively termed evapotranspiration (ET) because they co–occur. Evaporation is the process where liquid water is converted to water vapour and removed from sources such as open water, soil surface, wet vegetation, pavement, etc. Transpiration consists of the vaporisation of liquid water within a plant and subsequent loss of water as vapour through leaf stomata.

Potential evapotranspiration (ET_p) is a measure of the possibility for water to escape from earthy surfaces (soil, shallow water, plants, etc.) to the atmosphere through the processes of evaporation and transpiration under no water supply limitations. Actual evapotranspiration (ET_a) is a measure of the quantity of water that is actually removed from the earth cover surfaces to the atmosphere due to evaporation and transpiration. Water availability for the processes of evapotranspiration determine how much of the ET_p is realised. Potential evapotranspiration is also known as crop reference evapotranspiration (ET_O). It is an essential parameter to estimate crop water demand and defining drought and aridity. Clearly, ET_a cannot be greater than ET_p.

It is nearly impossible to directly measure evapotranspiration (Eagleman, 1967). Therefore, empirical methods and equations have been developed to estimate ET_p and ET_a.

There are many variations of the well-known Penman (1956) equation for the estimation of ET_p. Currently, the most used is the FAO Penman-Monteith equation (Allen *et al.*, 1998):

$$ET_p = \frac{0.408\Delta(R_n - G) + \gamma\frac{900}{T+273}u_2(e_s - e_a)}{\Delta + \gamma(1 + 0.34u_2)} \qquad 4\text{-}3$$

where
ET_p: reference evapotranspiration [mm day^{-1}]
R_n: net radiation at the crop surface [MJ m^{-2} day^{-1}]
G : soil heat flux density [MJ m^{-2} day^{-1}]
T: mean daily air temperature at 2 m height [°C]
u_2: wind speed at 2 m height [m s^{-1}]
e_s: saturation vapour pressure [kPa]
e_a: actual vapour pressure [kPa]
$e_s - e_a$: saturation vapour pressure deficit [kPa]
Δ: slope vapour pressure curve [kPa °C^{-1}]
γ: psychrometric constant [kPa °C^{-1}]

As can be deduced from Eq. 4-3, evapotranspiration processes depend on solar radiation, air temperature, relative humidity and wind speed (Zotarelli *et al.*, 2015). Energy received from the sun accounts for nearly 80% of the variation in potential

evapotranspiration. The second most important factor influencing potential evapotranspiration is wind, which enables the removal of water molecules from the earth cover surface into the atmosphere.

ET_p provides a standard to which evapotranspiration at different periods and/or areas can be compared and a reference value from which evapotranspiration of various crops can be calculated as it represents grass ET_O. Crop evapotranspiration (ET_c) is calculated by multiplying ET_p by a suitable crop coefficient (K_c). Variations of K_c account for various cropping conditions including type, growth, soil moisture and management practices.

4.5 Climatic data availability

4.5.1 Monitoring network

Long-term climatological records are available for Palmerston North city from two stations: (1) Palmerston North Aws which was discontinued after 31/05/2001, and (2) Palmerston North Ews which was commissioned on 1/04/2001. NIWA numbers and location information for these two climatic stations are provided in (Table 4-1). The new Station is located c. 6.35 km to the south east of the old station (Figure 4-5).

Table 4-1. Palmerston North climatic stations.

Name	Agent number	Network number	Latitude (dec.deg)	Longitude (dec.deg)	Height (masl)
Palmerston North Aws	3243	E05368	-40.325	175.611	39
Palmerston North Ews	21963	E0536D	-40.38195	175.60915	21

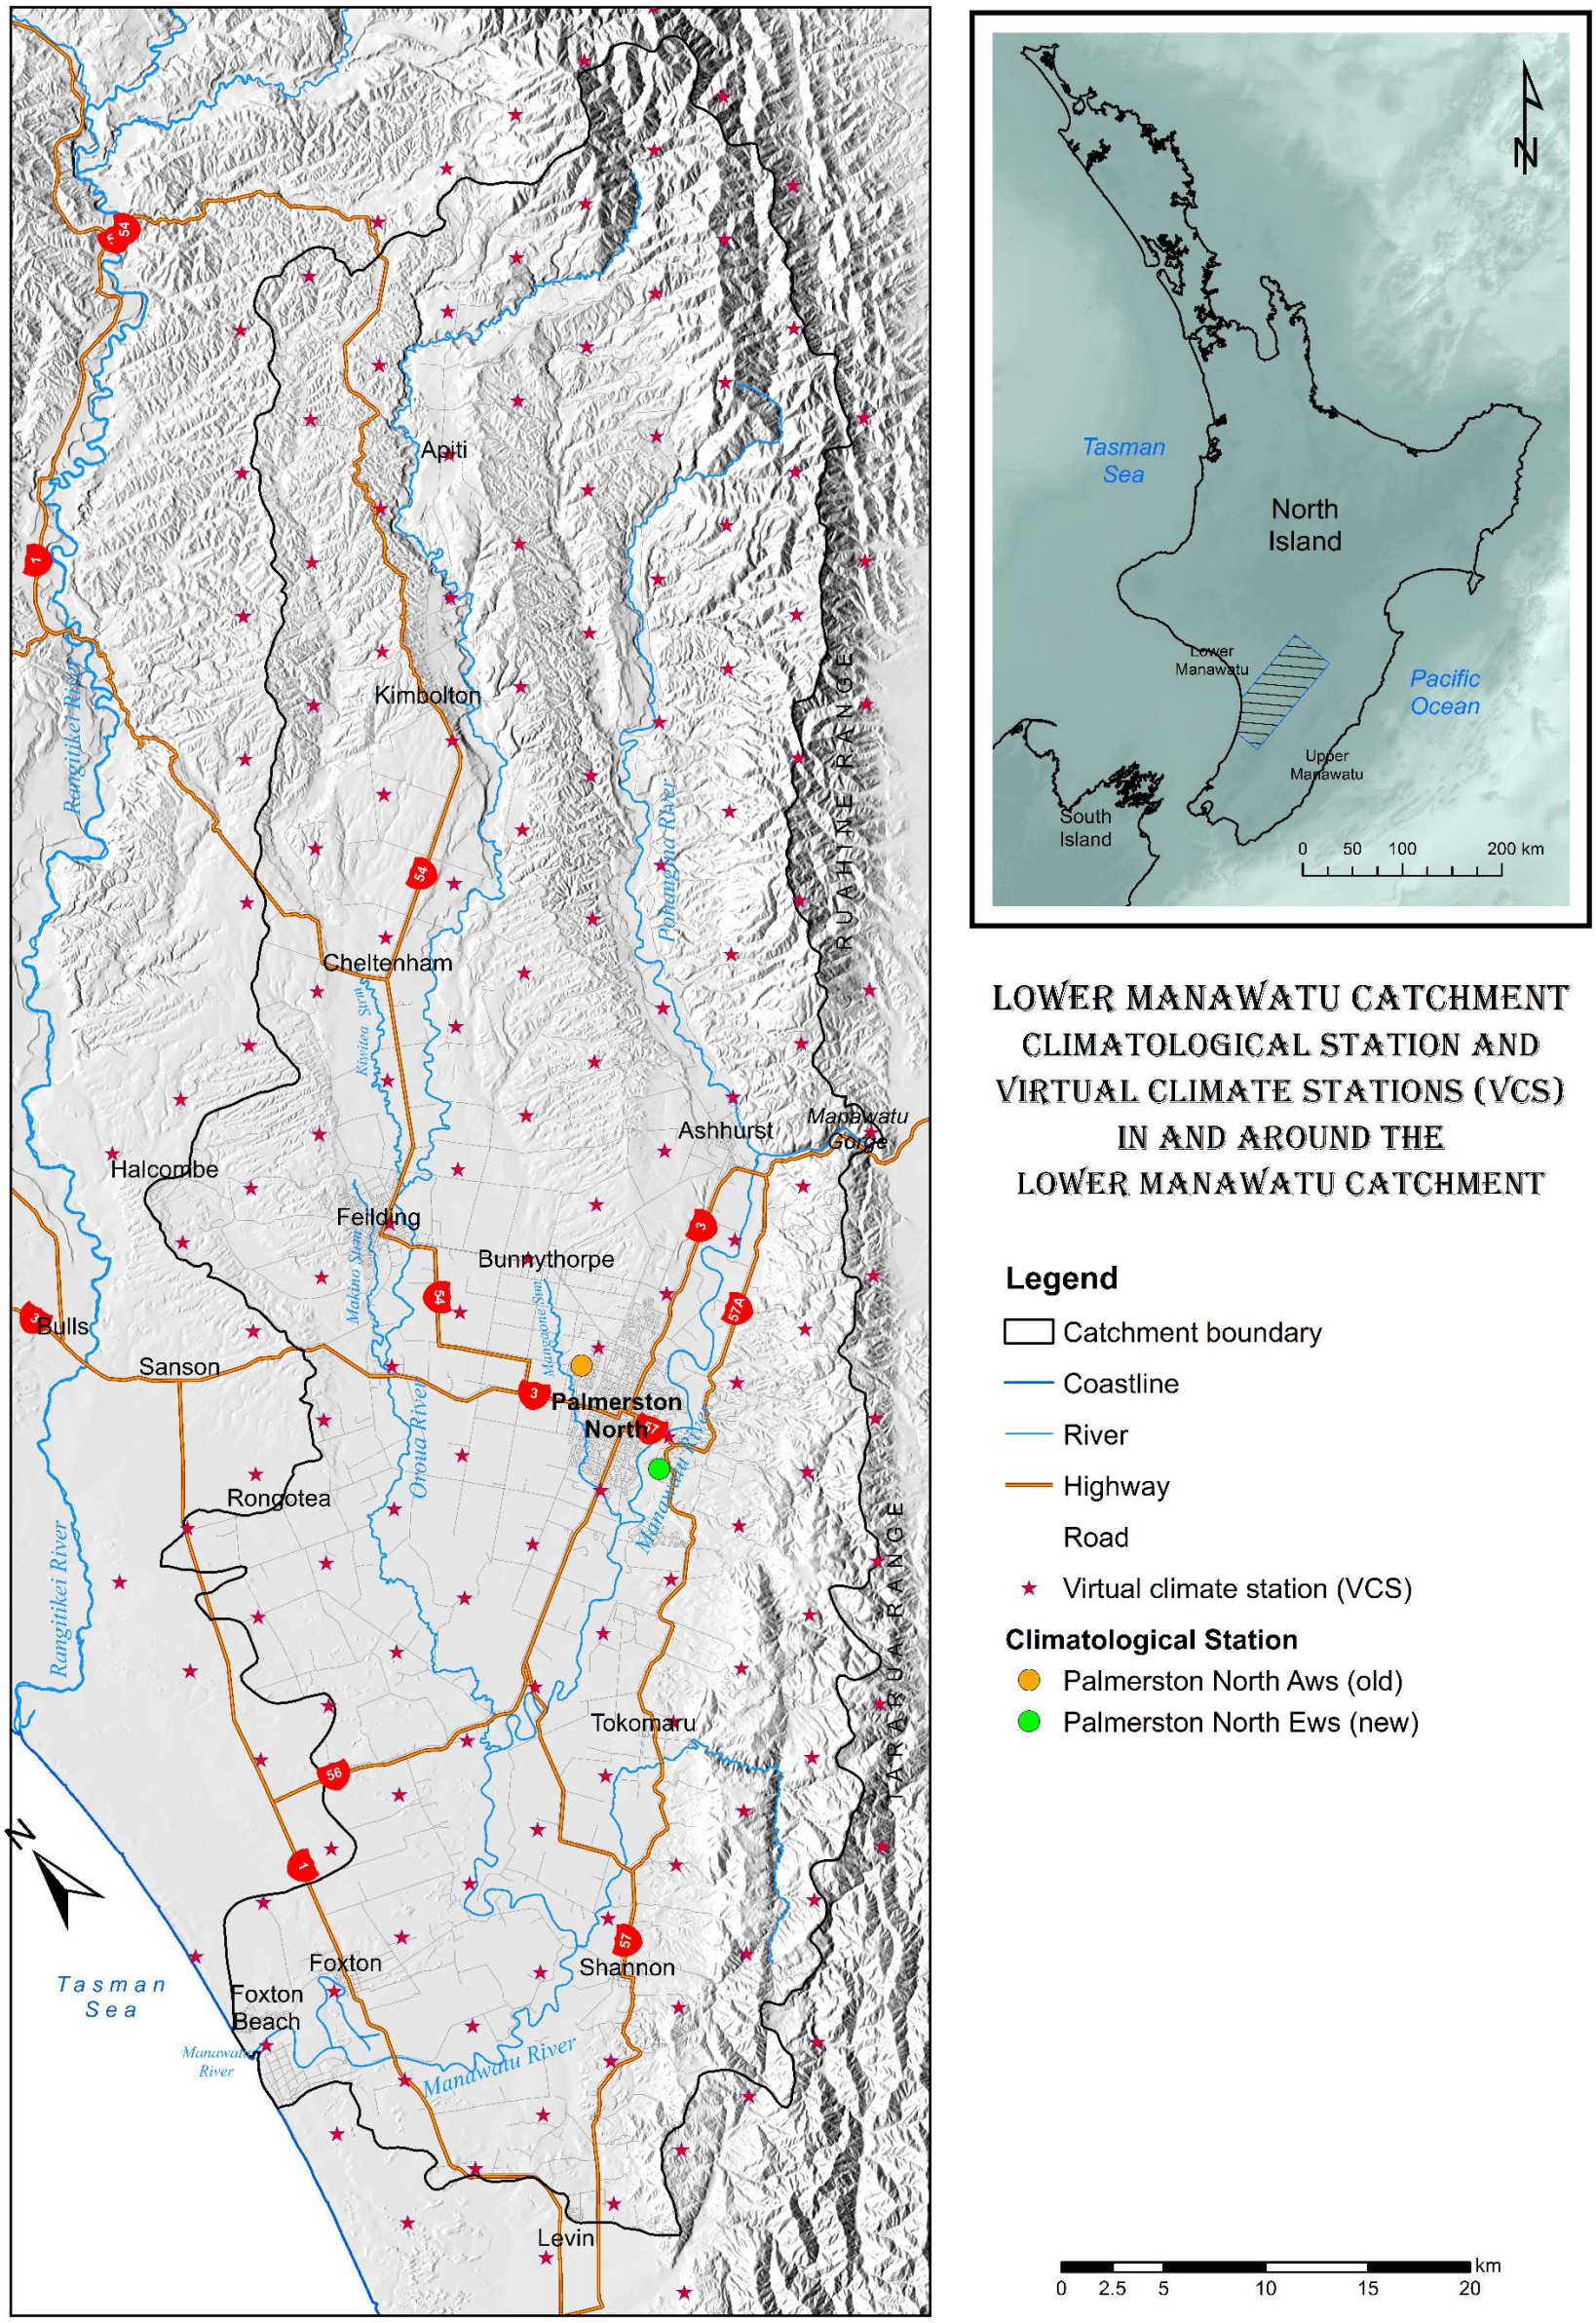

Figure 4-5. Climatic and virtual climatic stations in and near the LMC.

Palmerston North Aws and Ews climatic stations coincided for two months (April – May 2001). During the overlap period, daily rainfall reported for the two stations slightly differs (Table 4-2). The old station recorded 6.5 mm of rain less than the new station, which is mostly related to rain on 12/04/2001. In May 2001, however, the old station recorded 11.9 mm of rain more than the new station. The old station recorded 5.4 mm of rain more than the new station over the overlap period. On 22/05/2001, both stations recorded the same amount of rainfall, 1.2 mm.

Table 4-2. Reported daily rainfall for stations Palmerston North Aws (old) and Palmerston North Ews (new) during their co-operating period.

4.5.2 Virtual climate stations

NIWA calculates estimates of daily rainfall, potential evapotranspiration, air and vapour pressure, maximum and minimum air temperature, soil temperature, relative humidity, solar radiation, wind speed and soil moisture on a regular (c. 5 km) grid covering the whole of New Zealand. The estimates are based on spatial interpolation of actual data observations made at climate stations distributed around the country. The centroids of the grid cells represent a network of virtual climate stations (VCSs). VCSs in and around the LMC are shown in (Figure 4-5). In the LMC, synthetic VCS data largely agree with actual measurements from physical climate stations.

VCS data consist of two unique station identifiers – the 'agent' and the 'network', date, barometric pressure reduced to mean sea level in hPa, Penman potential evapotranspiration depth in mm, rainfall depth in mm, relative humidity in percent, earth temperature at 10 cm depth in °C, amount of accumulated global solar

radiation in Mega Joules per square metre, maximum air temperature in °C, minimum air temperature in °C, vapour pressure in hPa, mean wind speed in m/s at 10 m above ground level, and soil moisture deficit (SMD) depth in mm calculated from rainfall and evapotranspiration. The base value is 150 mm SMD (hypothetical unified permanent wilting point) based on soil store capacity. SMD value of 0 indicates the soil is at field capacity. SMD value less than zero indicates deep percolation, i.e. groundwater recharge (Section 4.3.4).

NIWA made LMC VCS data available for this thesis. VCS rain data are available from 1/01/1960, wind speed data from 1/01/1997, and all other variables from 1/01/1972. However, only VCS rain, potential evapotranspiration and soil moisture data were analysed in this research for the period 1/01/1985–31/12/2015, inclusive (31 years). The period 1985–2015 has been selected for analysis in this thesis because useful groundwater level data extend from 1990 to the present. Starting climatological analysis five years earlier enables comfortable accounting of the time lag between rainfall and groundwater level response.

4.6 LMC climate

4.6.1 General setting

The LMC location between latitudes 39° 52' 30" and 40° 39' 00" South gives it temperate climate. In general, the area enjoys a mild climate with moderate seasonal variations.

The National Institute of Water and Atmospheric Research (NIWA) subdivides New Zealand land into broad climate zones and the LMC falls within the South-West North Island zone, which includes Taranaki, Manawatu-Wanganui and Wellington regions. This zone is exposed to disturbed weather systems from the Tasman Sea and although it is relatively windy, climatic extremes are rare and limited. The inland parts of the zone, with greater orographic influence, are more prone to climatic extremes. The most settled weather in the zone occurs during summer and early autumn, with winter normally the most unsettled time of the year.

North-westerly airflows prevail over the area. Sea breezes occasionally occur along the coast during summer. Frost occurs inland in winter during clear calm conditions. In average, air temperature exceeds 25°C in Palmerston North 25 days per year and drops below zero centigrade 16 days per year (Chappell, 2015). Table 4-3 presents mean climatological characteristics for Palmerston North, which is situated nearly in the centre of the LMC.

4.6.2 Precipitation

Rainfall is the dominant type of precipitation in the LMC, snow being very rare on most of the area, particularly the plains. The area does not experience the severity of droughts that affect some other parts of New Zealand.

Tait and Sturman (2008) prepared mean and median annual rainfall maps for the Horizons region for the two overlapping 30-year periods of 1971-2000 and 1978-2007 at 500 m spatial resolution using all data archived at the time in NIWA's National Climate Database (CliFlo) and additional data supplied by Horizons. Extracts for the LMC area from these four maps are reproduced in Appendix A and Figure 4-6 presents mean annual rainfall isohyetal map for the period 1971-2000 based on their work. Tait and Sturman (2008) chose the period 1971-2000 because it is the latest climate 'normal' period at the time. But since that period does not include more recent years that include some anomalously high or low rainfalls, they also analysed and prepared rain maps for the 'most recent' 30-year period at the time, being 1978-2007.

Tait and Sturman (2008) rain maps were prepared using the thin plate smoothing spline model in the ANUSPLIN software package. The maps which are reproduced in Appendix A show that the mean annual rainfall over the LMC ranges between around 810 mm/y in the Bunnythorpe and Awahuri area, to more than 3,000 mm/y in the in the Ruahine Range to the northeast of LMC.

Table 4-3. Long-term mean climatic parameter values for Palmerston North (mainly compiled from Chappell, 2015)[21].

Climatic Parameter	Units	Jul	Aug	Sep	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Year
Mean number of wet days[22]	days	12	13	12	12	10	11	7	7	8	8	10	12	122

[21] Italic type font indicates data compiled from NIWA's National Climate Database (CliFlo).
[22] Days with 1 mm or more of rain. Mean annual number of days with 0.1 mm or more of rain = 171.
[23] Measured at 10 cm depth.
[24] Measured at 9.00 am.
[25] Yearly minimum, maximum and mean potential evapotranspiration values are not calculated from monthly data, but for actual annual totals.

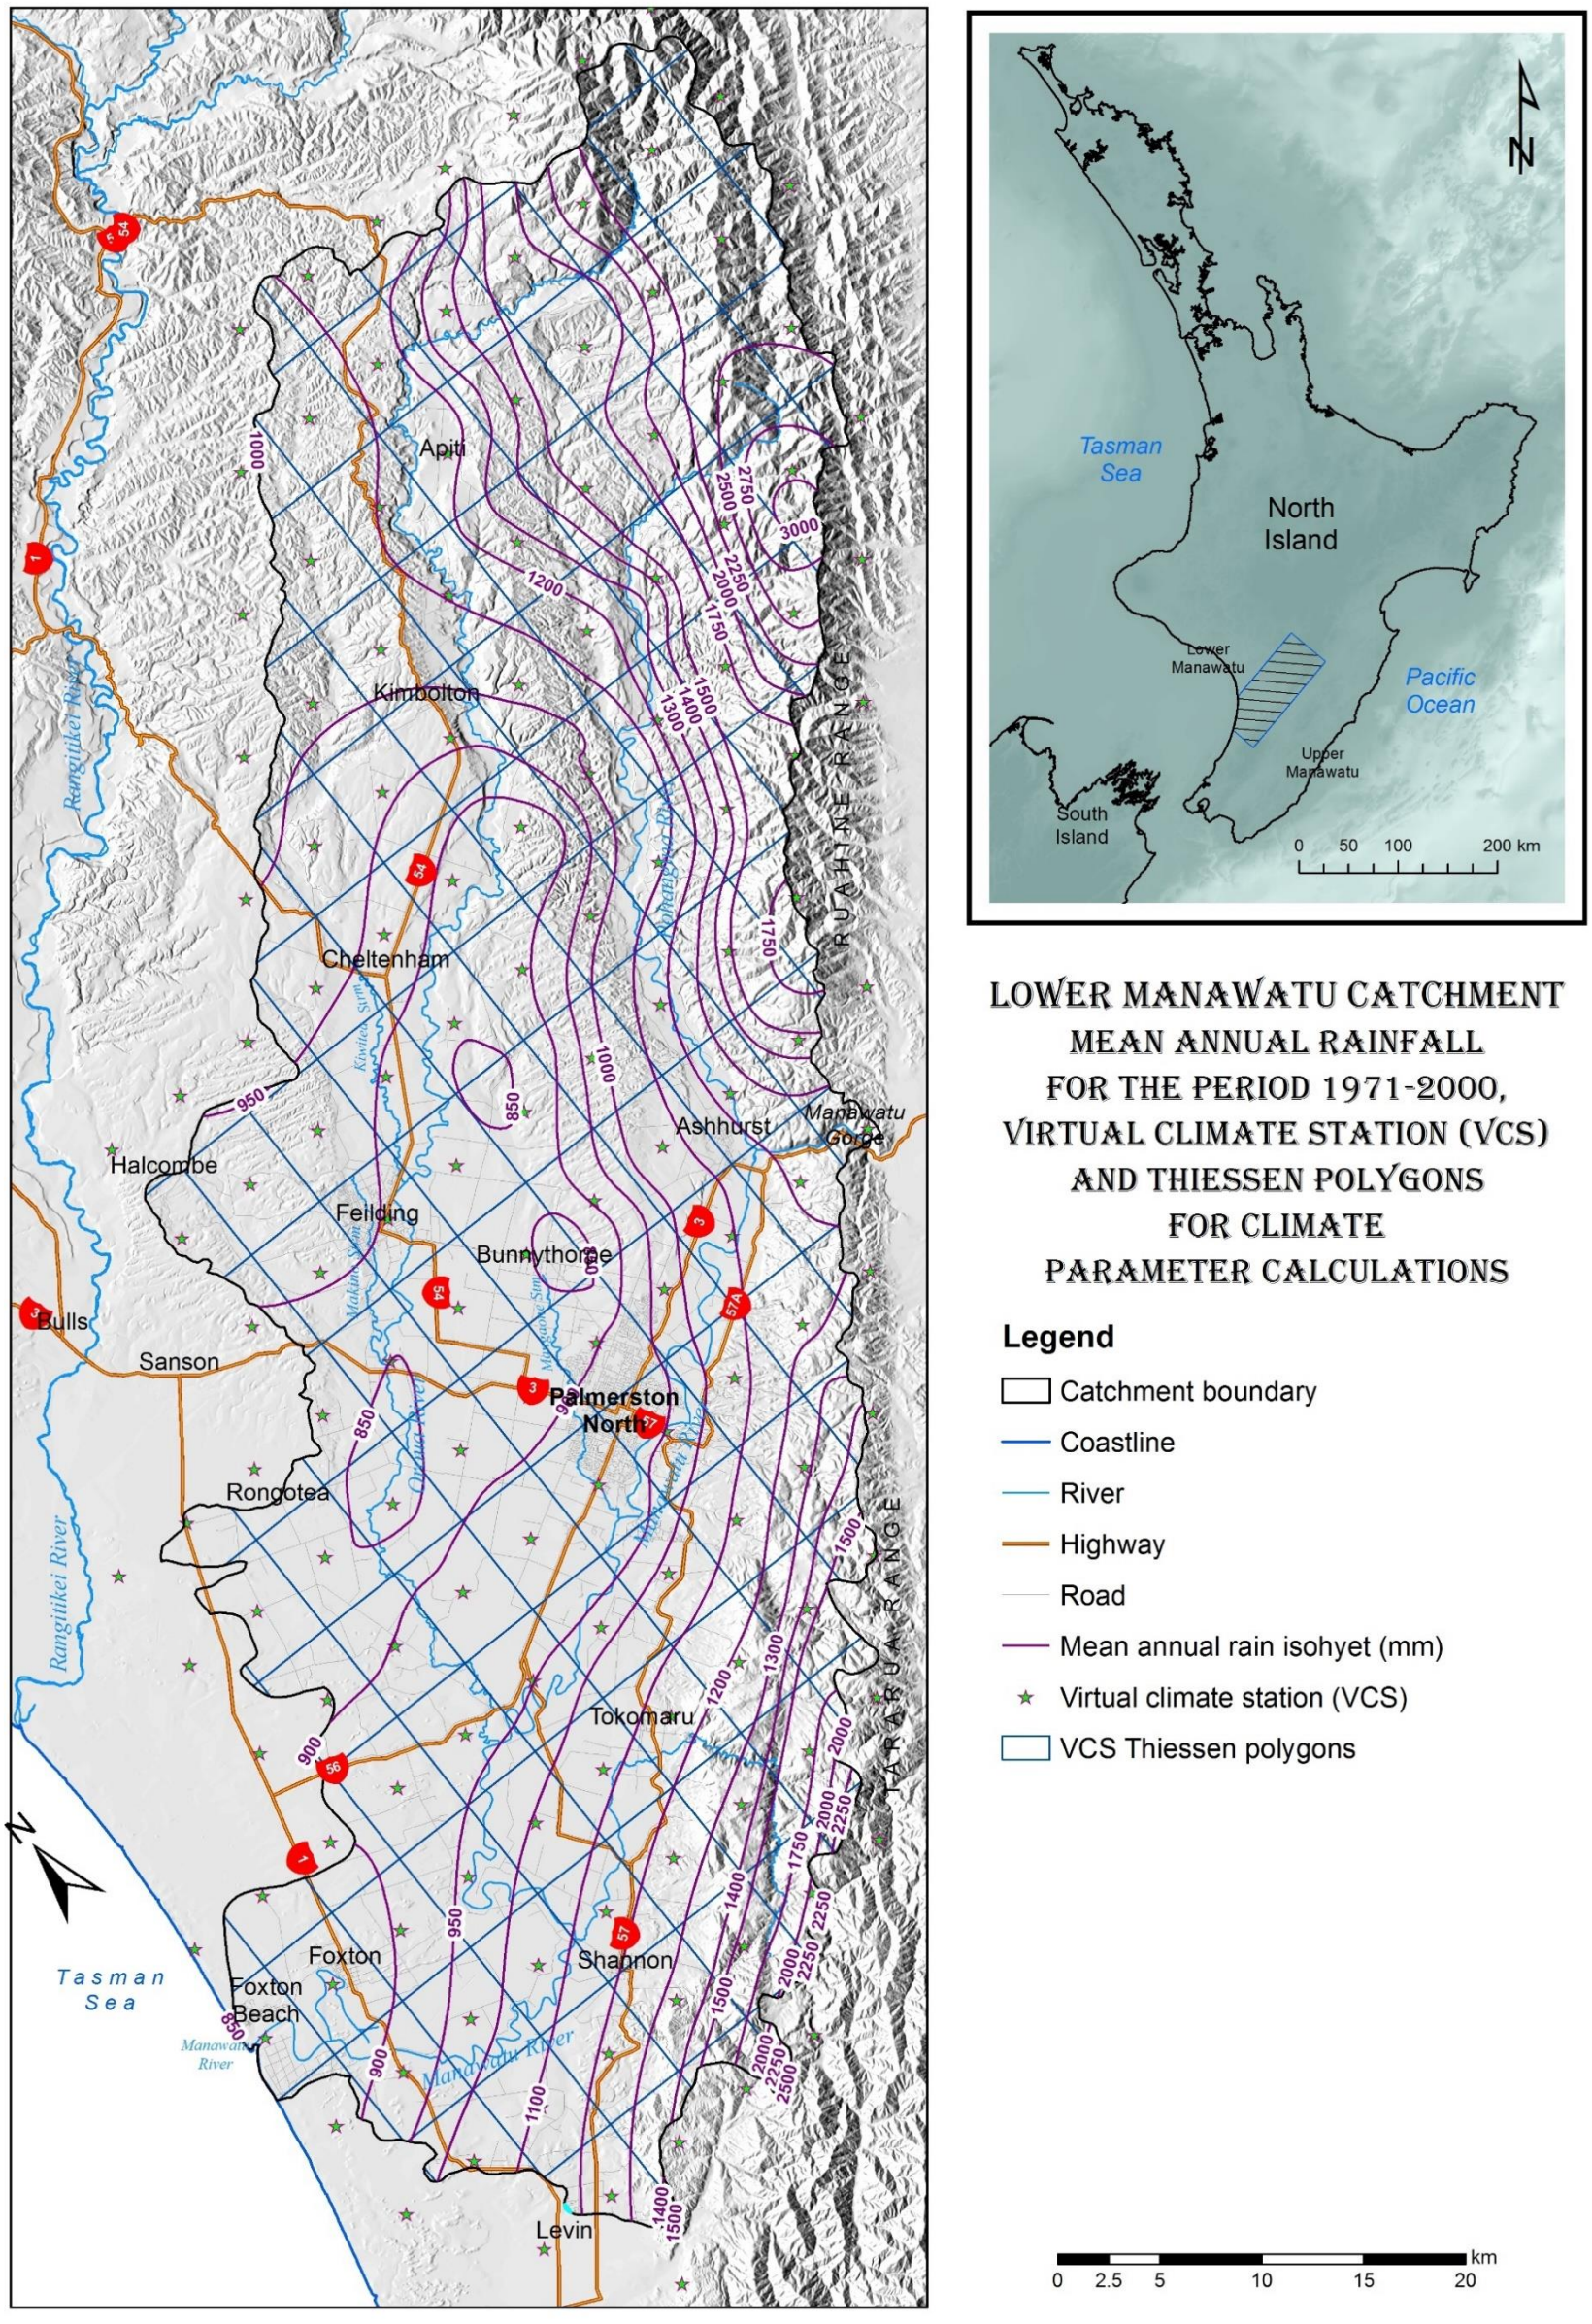

Figure 4-6. Virtual climate stations (VCS), Thiessen polygons for climatic parameter calculations and mean annual rainfall isohyetal map for the period 1971-2000 (based on digital map by Tait & Sturman, 2008).

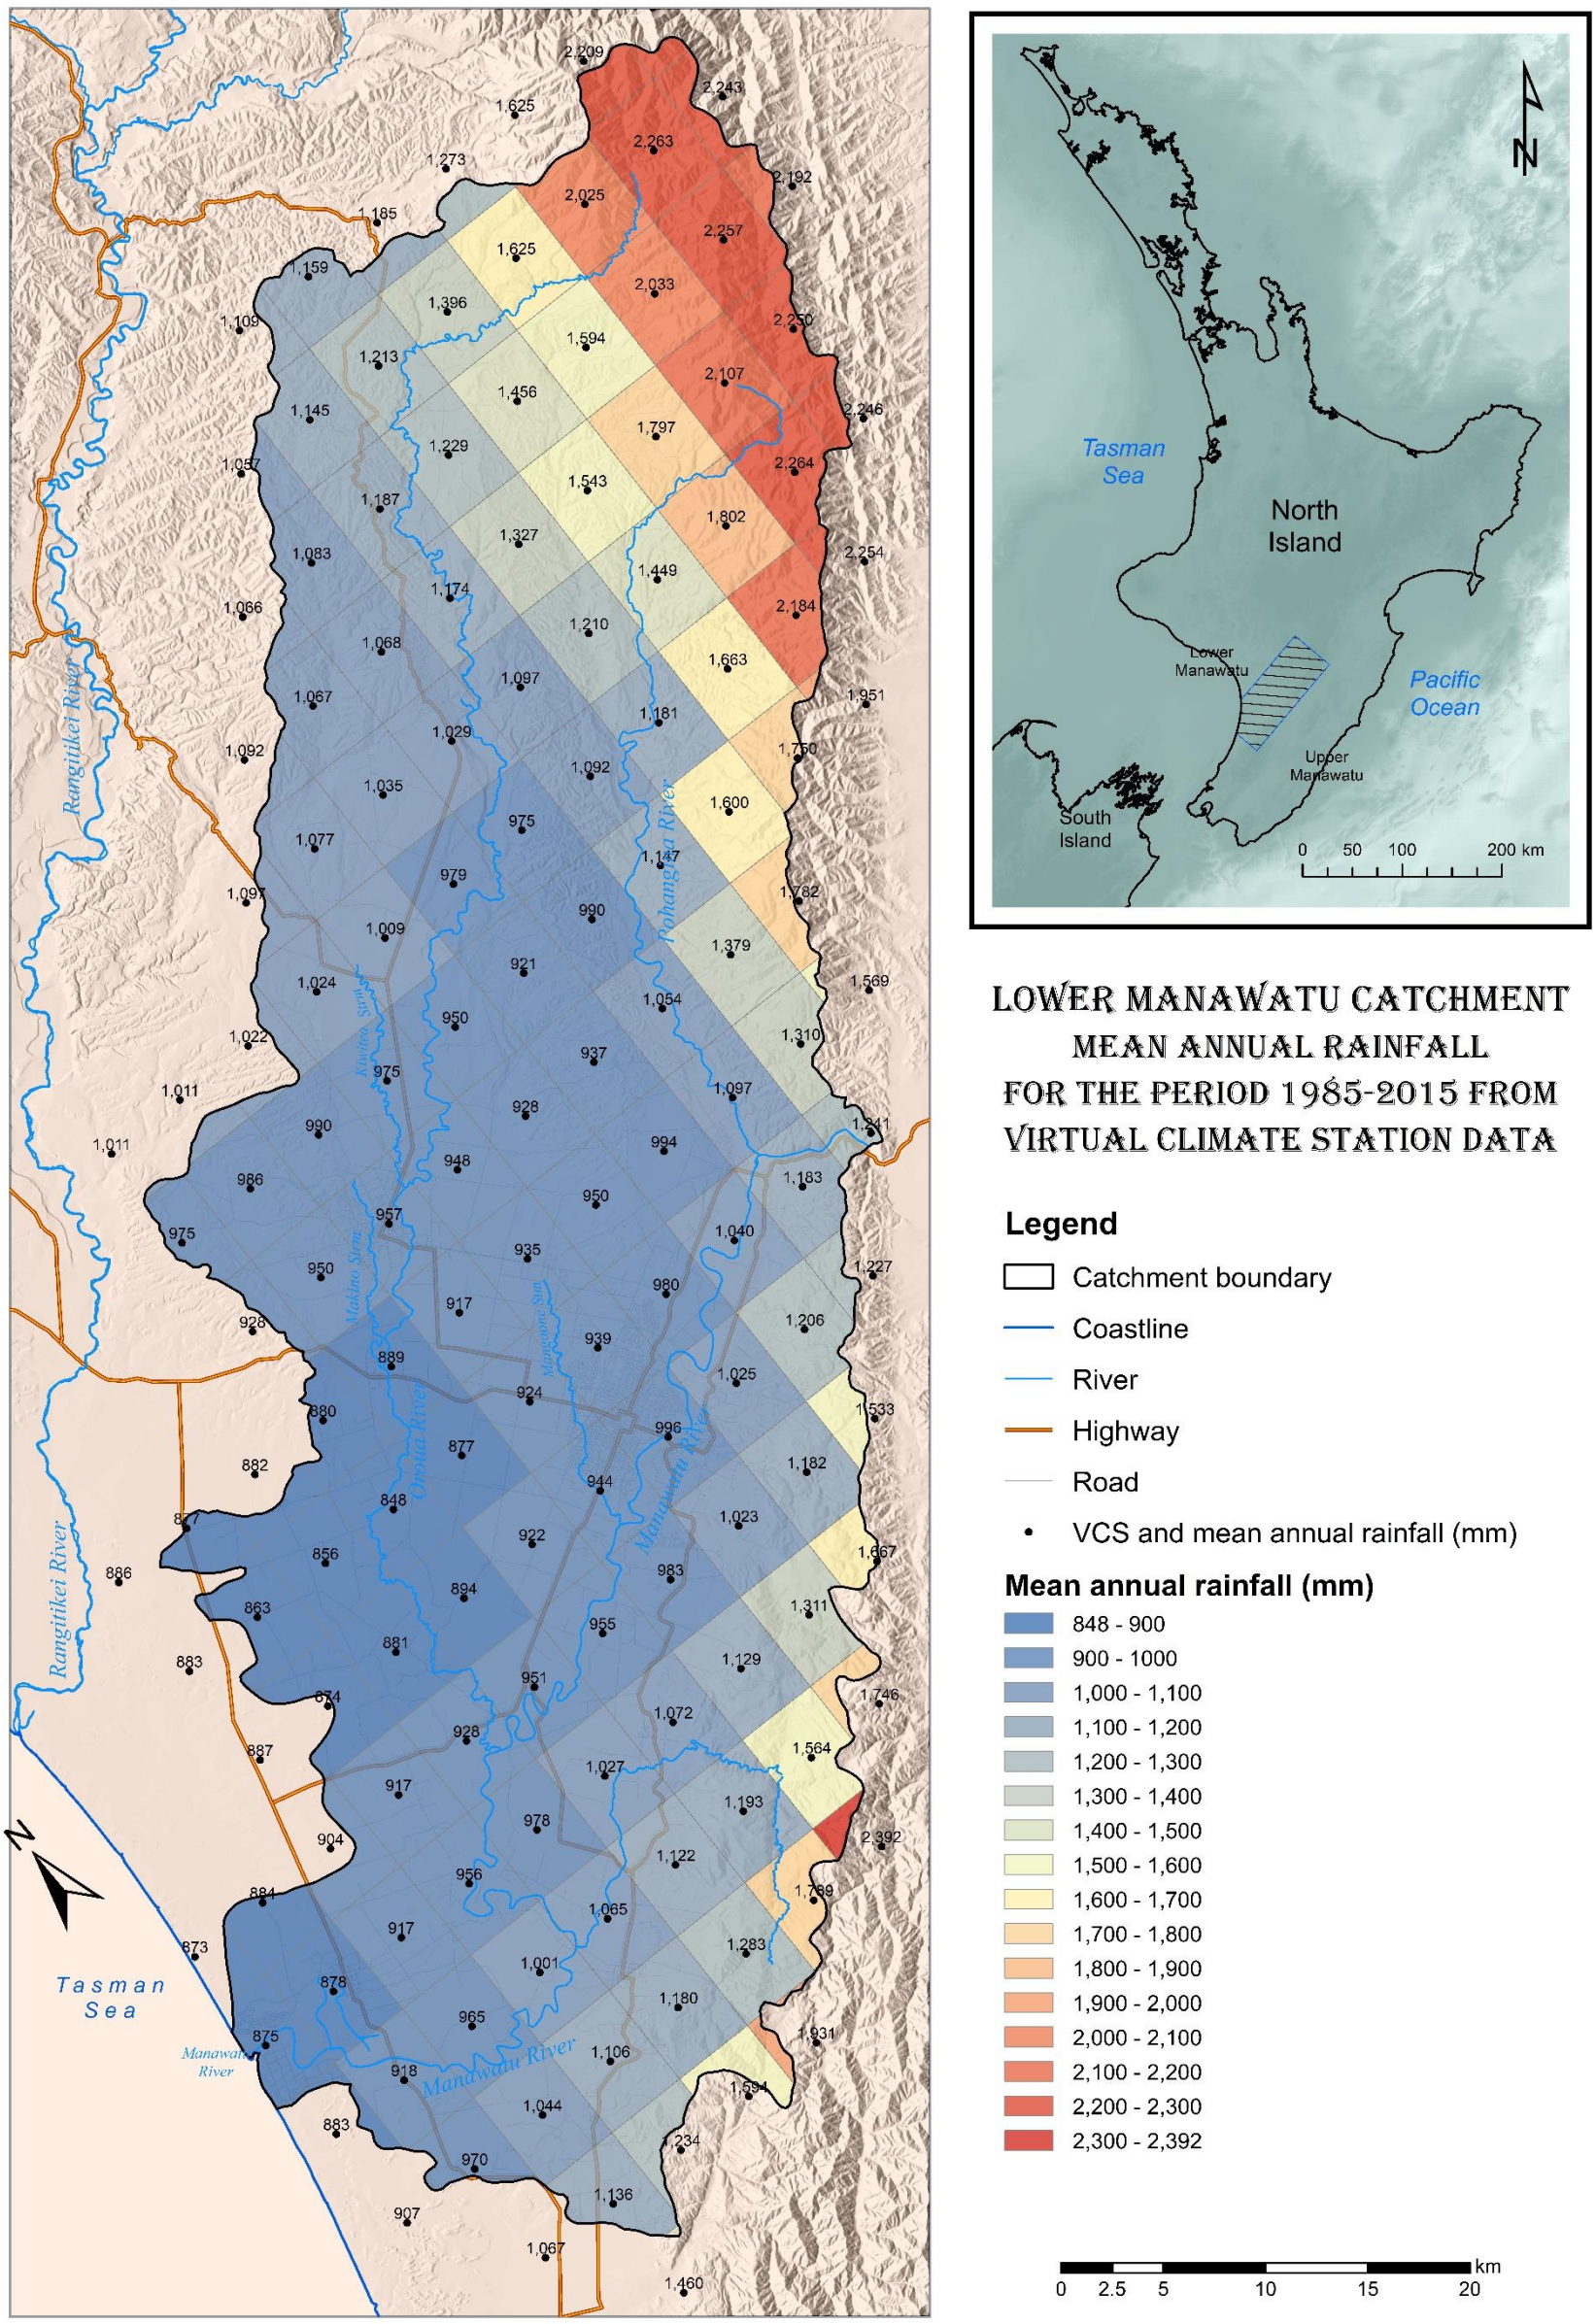

Figure 4-7. Mean annual rainfall calculated from VCS data for the period 1985 – 2015.

NIWA statistics indicate that rain falls on Palmerston North approximately 5% of the time and that, on average, the city enjoys 200 rain free days per year.

To estimate mean annual rain over the LMC area, Thiessen polygons were drawn around VCSs to identify the area of representation for each of them (Figure 4-6). The results are summarised in Table 4-4 and presented graphically in Figure 4-7.

Table 4-4. Annual mean rain rates and volumes over the LMC area for the periods 1985-2015 calculated from VCS data.

Catchment	Area (m^2)[26]	Rain	
		Mean (mm)	Total (mcm[27])
Pohangina	547,828,093	1,567.37	858.65
Oroua	910,284,347	1,150.26	1,047.06
Manawatu-Lower	1,206,437,484	1,052.30	1,269.54
Overall (LMC)	2,664,549,924	1,191.66[28]	3,175.25

Mean annual rainfall over Palmerston North calculated using VCS data ranges between c. 925 mm and c. 995 mm, decreasing from southeast to northwest (Figure 4-7). Mean annual rainfall volumes and rates calculated for the LMC over the period 1985-2015 from VCS data (Table 4-4) slightly differ from estimates extracted from Tait and Sturman (2008) rain maps (Table 4-5), with the difference being around 1.5%.

Table 4-5. Mean and median rain rates and volumes over the LMC area for the periods 1971-2000 and 1978-2007 (estimated from digital maps by Tait & Sturman, 2008).

LMC annual rain	1971-2000		1978-2007	
	mean	median	mean	median
Total Volume (mcm/y)	3,242	3,248	3,233	3,210
Depth (mm/y)	1,210	1,212	1,207	1,198

Figure 4-8 presents monthly rain recorded for Palmerston North over the period 1985-2015, which averages to c. 80 mm/month compared to c. 76 mm/month over the period 1971-2007 as calculated by Tait and Sturman (2008).

[26] This estimation is smaller than the LMC area estimation in other parts of the thesis due to discounting some of the area covered by rivers, particularly the Manawatu River.
[27] mcm: million cubic metre.
[28] Geographic weighted mean, calculated by dividing total rain volume by area.

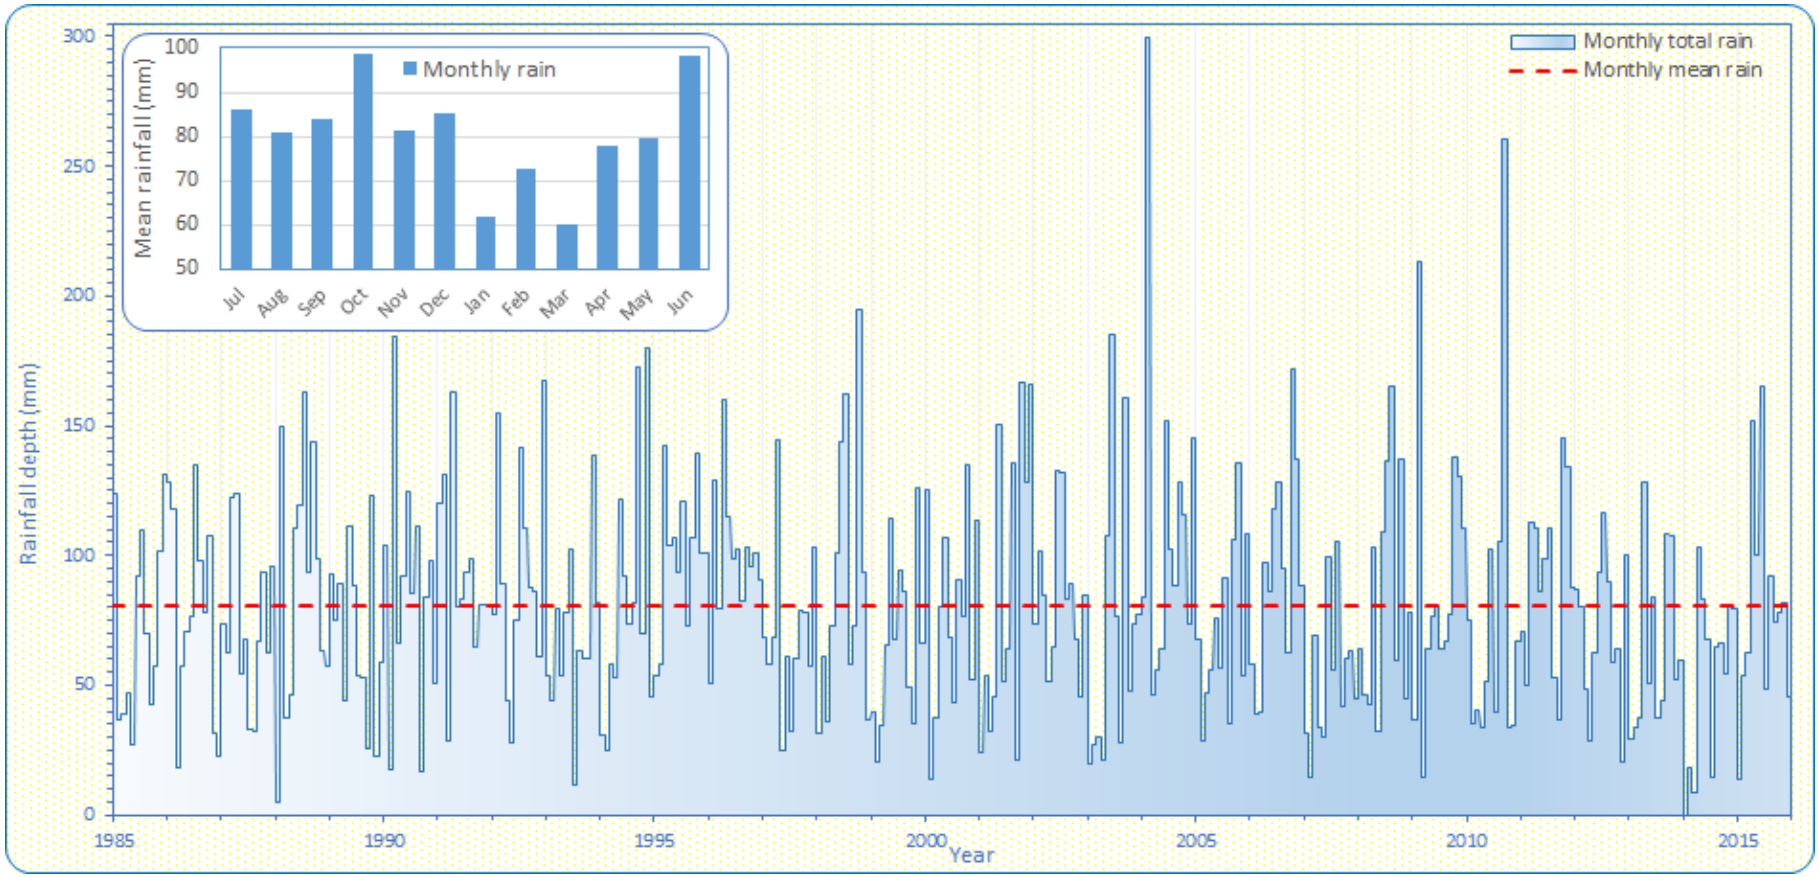

Figure 4-8. Monthly rainfall at Palmerston North for the period 1985-2015.

Inset presents long-term mean monthly rainfall for the same period. Data for the period 1/01/1985-31/05/2001 from Palmerston North Aws Station (NIWA agent number 3243). Data for the period 1/06/2001-31/12/2015 from Palmerston North Ews Station (NIWA agent number 21963). Inset presents monthly average rainfall for the same period.

The data presented in Figure 4-8 suggest a greatly variable, unpredictable rainfall pattern in the LMC. During the period 1985-2015, the highest annual rainfall (c. 1,355 mm) was recorded in 2004 and the lowest (641 mm) in 2014 (Figure 4-9 Top). The inset plot in Figure 4-8 indicates that the driest months in the year in average are the summer months January-March. Noticeably, the maximum monthly rainfall (c. 300 mm) was recorded in summer, in February 2004 (Figure 4-8).

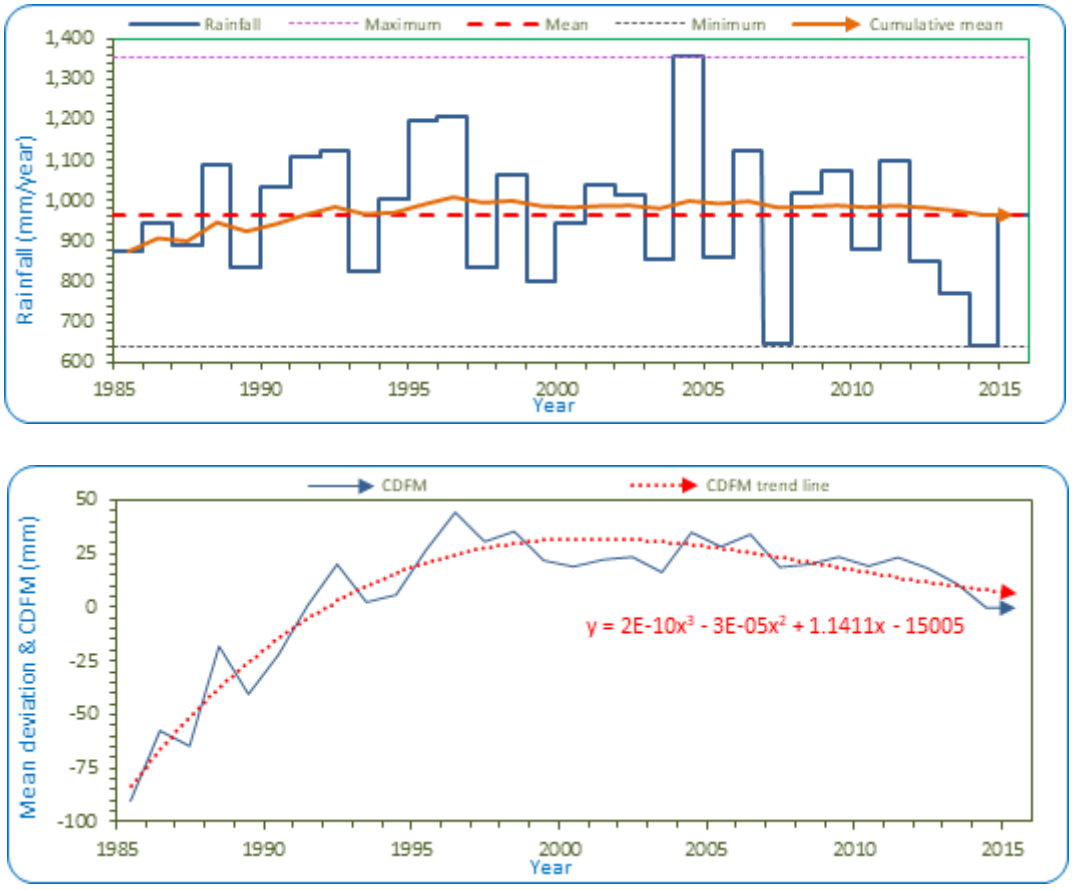

Figure 4-9. Yearly rainfall at Palmerston North.

Top: yearly total, maximum, mean, minimum and cumulative mean.

Bottom: Annual cumulative deviation from mean (CDFM), showing increasing rainfall until 1996, relative stability during the period 1996-2007, followed by a slight decrease until end of 2015.

Figure 4-9 (bottom) shows monthly rainfall cumulative deviation from mean (CDFM) at Palmerston North for the period 1985-2015 and Figure 4-10 shows monthly rainfall CDFM for the same period. The plots suggest that rainfall over Palmerston North has been trending upwards from 1988 until 2006. From 2006-2012, rainfall

has been constant, but dropped after that to a record low in 2014. The trend noticed in Palmerston North rainfall seems to exemplify rainfall over the entire LMC area. Correspondingly, groundwater levels over the period 1988–2012 in the LMC are expected to be higher than their long-term averages.

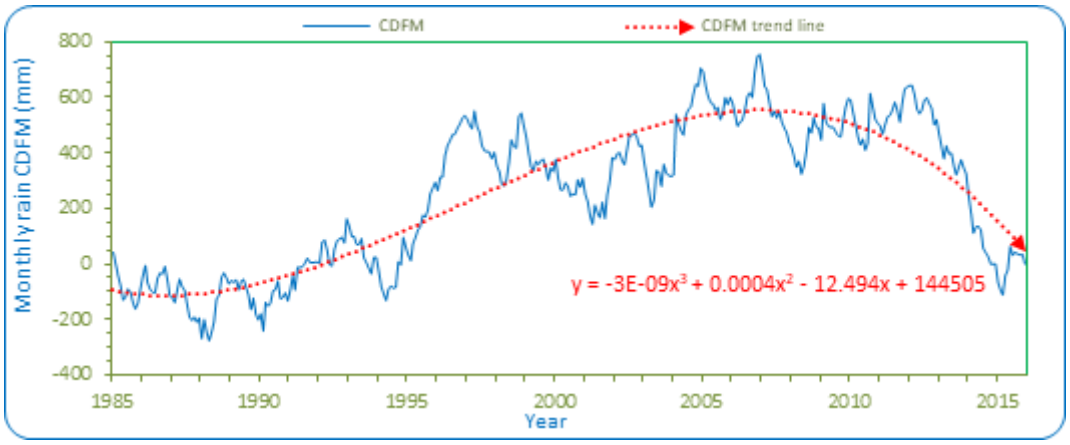

Figure 4–10. Monthly rain cumulative deviation from mean (CDFM) at Palmerston North for the period 1985–2015.

4.6.3 Evapotranspiration

The coastal area of the LMC has an average of about 2,000 sunshine hours a year but Palmerston North is defined as cloudy with an average of only 1,725 sunshine hours a year. In 1992, Palmerston North claimed the national low record of only 1,357 sunshine hours.

Summer in the LMC is warm, with a maximum mid-summer daily average air temperature of around 20–23 °C. The minimum mid-winter daily average temperature for the coastal area is a cool 4–8 °C, while inland areas are considerably colder.

Westerly breeze prevails in the area. It can be stronger in spring but rarely reaches gale force. The mountains that bound the catchment from two sides arguably provide the most consistent wind in New Zealand, especially in spring.

Palmerston North meteorological stations do not measure pan evaporation and NIWA's CliFlo database does not include ET_p data. However, NIWA calculates ET_p

as part of their VCS network climatological modelling (Section 4.5.2). Figure 4-11 shows the spatial distribution of potential evapotranspiration across the LMC. Generally speaking, ET_p is highest in the LMC in areas classified as open low hills landform type and gentler topography as delineated in Section 3.9.

Chappell (2015) calculated minimum, mean and maximum monthly ET_p for Palmerston North (Table 4-3). Figure 4-12 shows that potential evapotranspiration normally exceeds rainfall in Palmerston North during the period from October to March, which indicate a need to irrigate crops during that period. During most of this season (November-March), mean monthly rain is even less than the mean monthly minimum potential evapotranspiration. Albeit, Palmerston North has an overall average rain surplus of 86.4 mm/y as calculated from values presented in Table 4-3.

Figure 4-13 shows the mean annual difference between rainfall and potential evapotranspiration calculated from VCS data for the period 1985-2015. A general deficit can be seen in a relatively small area around the Halcombe Anticline between Bunnythorpe and Rongotea, indicating little to no possibility for groundwater recharge in that area.

VCS data calculations (Table 4-4) suggest that mean annual rain in the LMC is generally higher than mean annual potential evapotranspiration by c. 360 mm, the equivalent to c. 965 million cubic metre per year (mcm/y) over the catchment area. In reality, however, the surplus is greater because actual evapotranspiration is less than potential evapotranspiration during nearly half of the year. Soil water balance modelling results presented in Section 4.7.2 imply that over the LMC area rainfall exceeds actual evapotranspiration (ET_p) by c. 590 mm/y, the equivalent to c. 1,580 mcm/y. This surplus water is available for runoff and groundwater recharge.

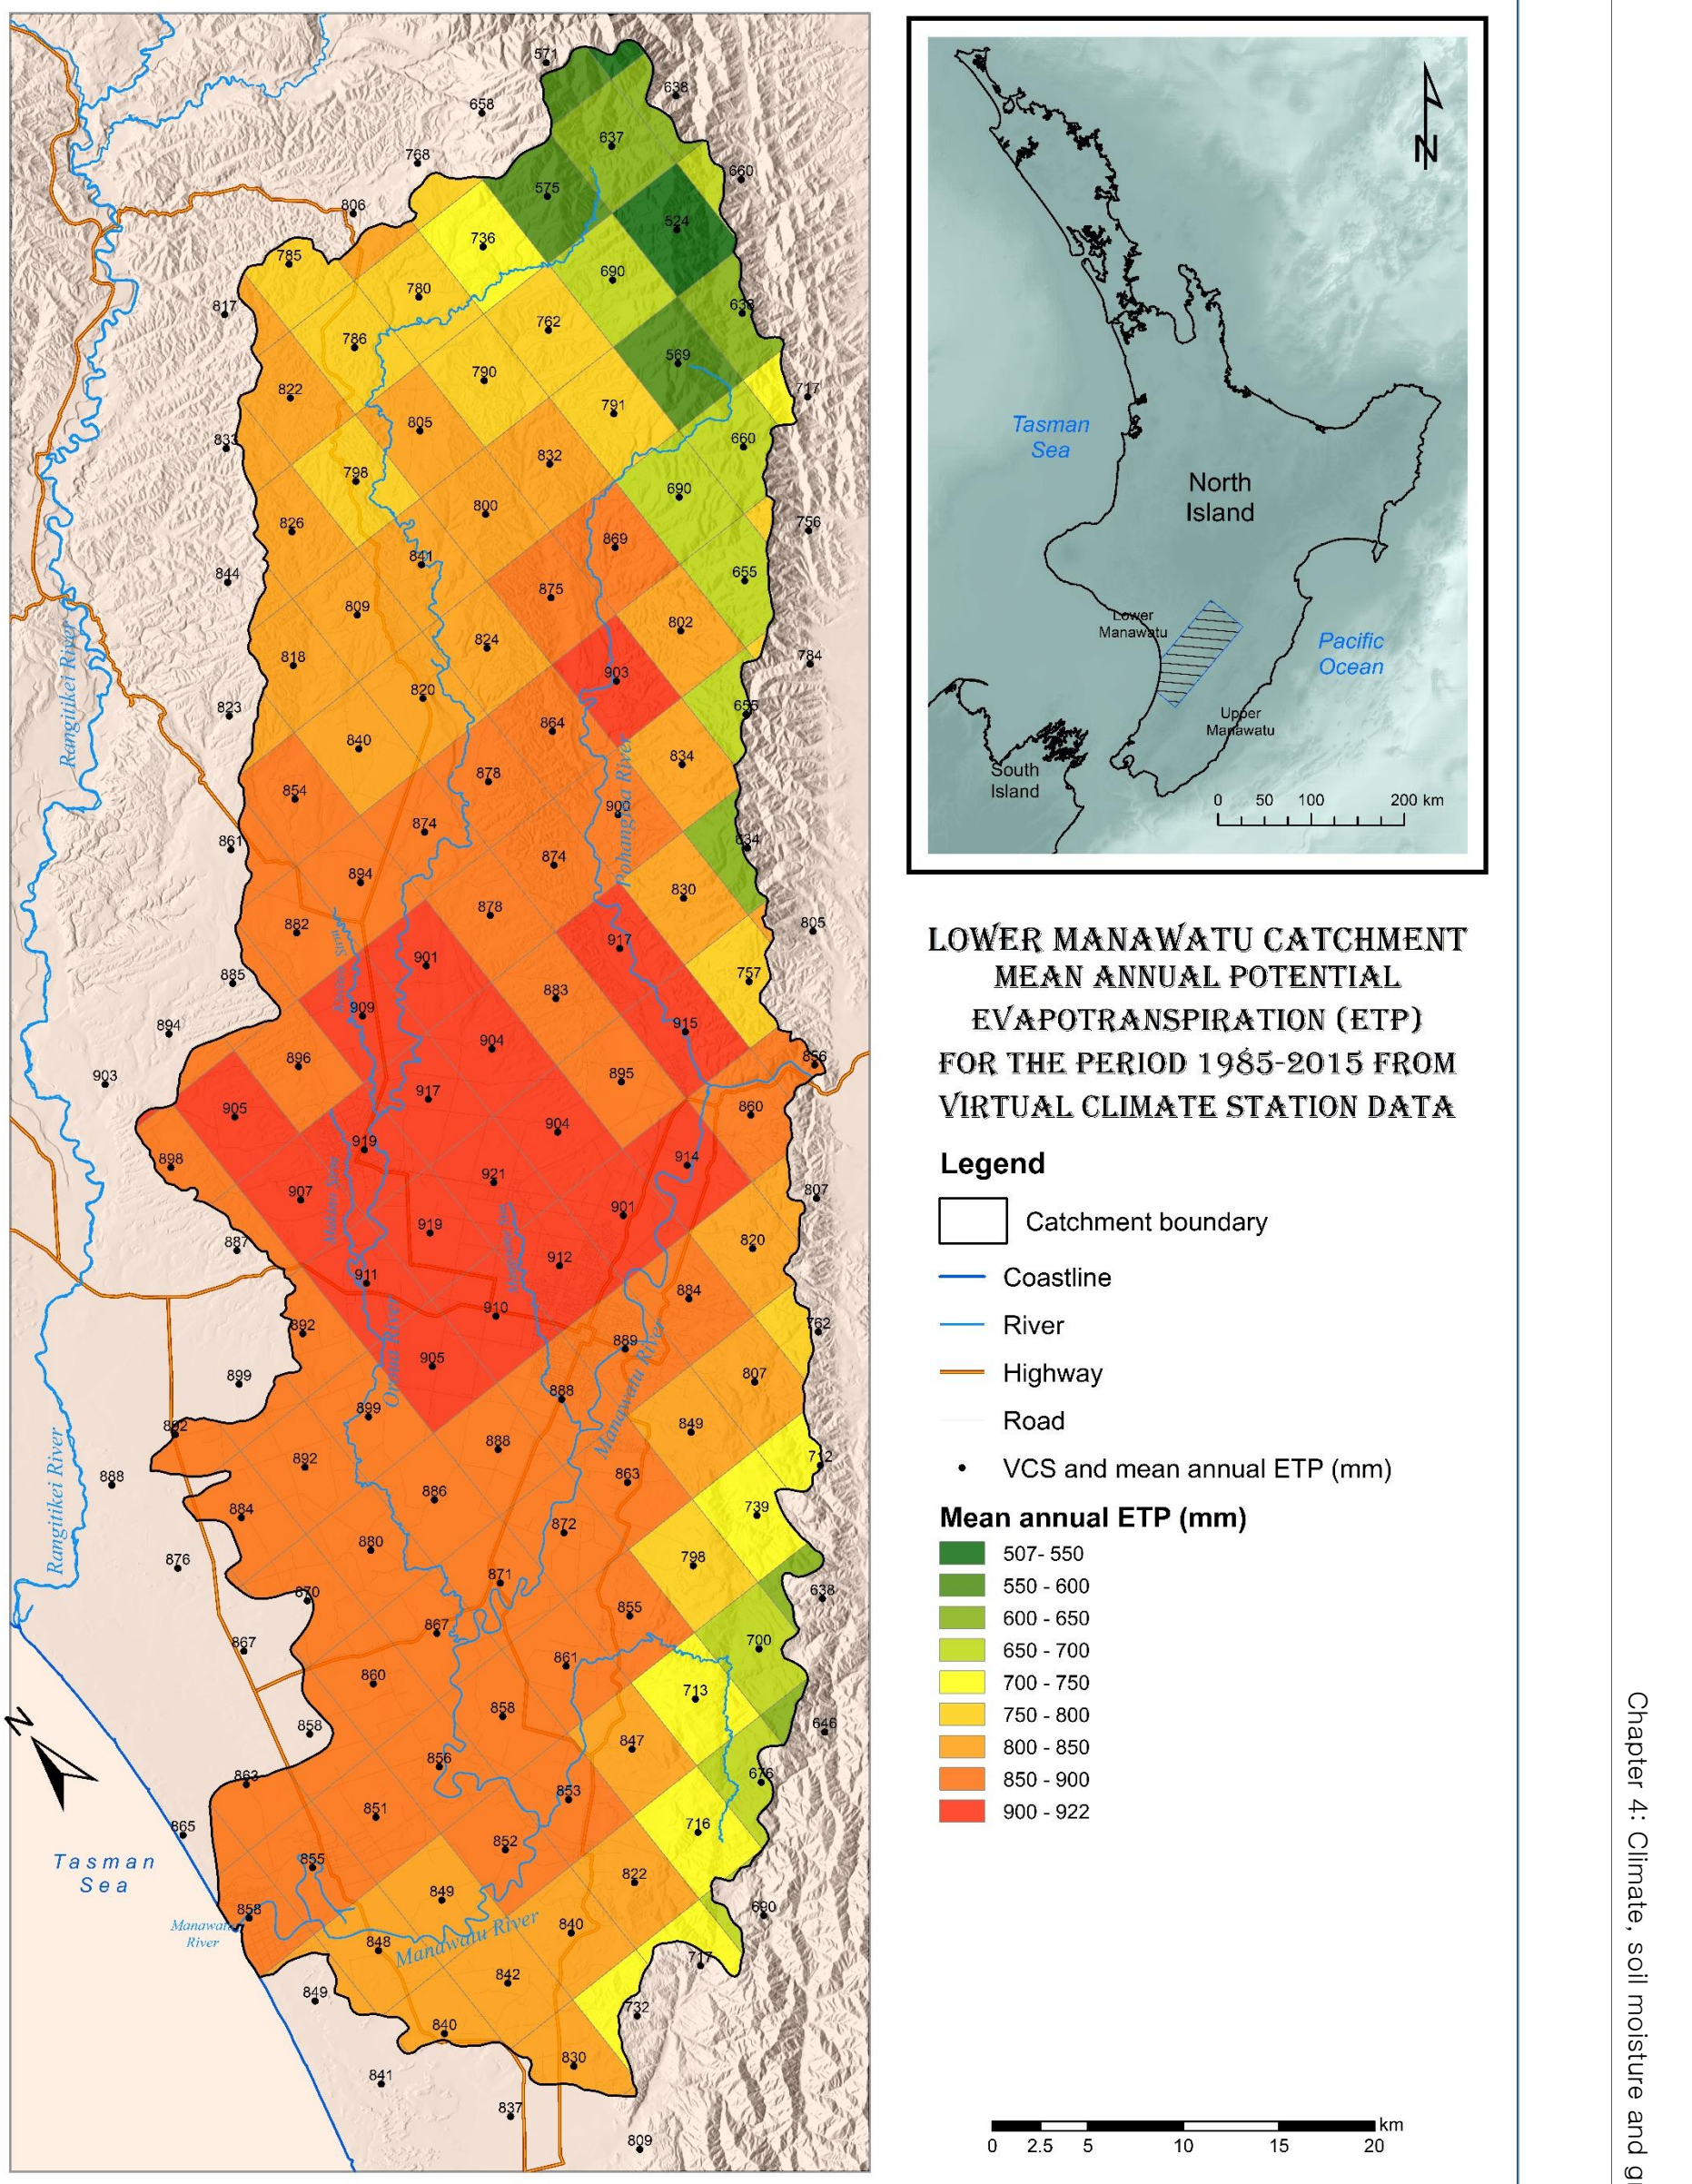

Figure 4-11. Mean annual potential evapotranspiration calculated from VCS data for the period 1985 – 2015.

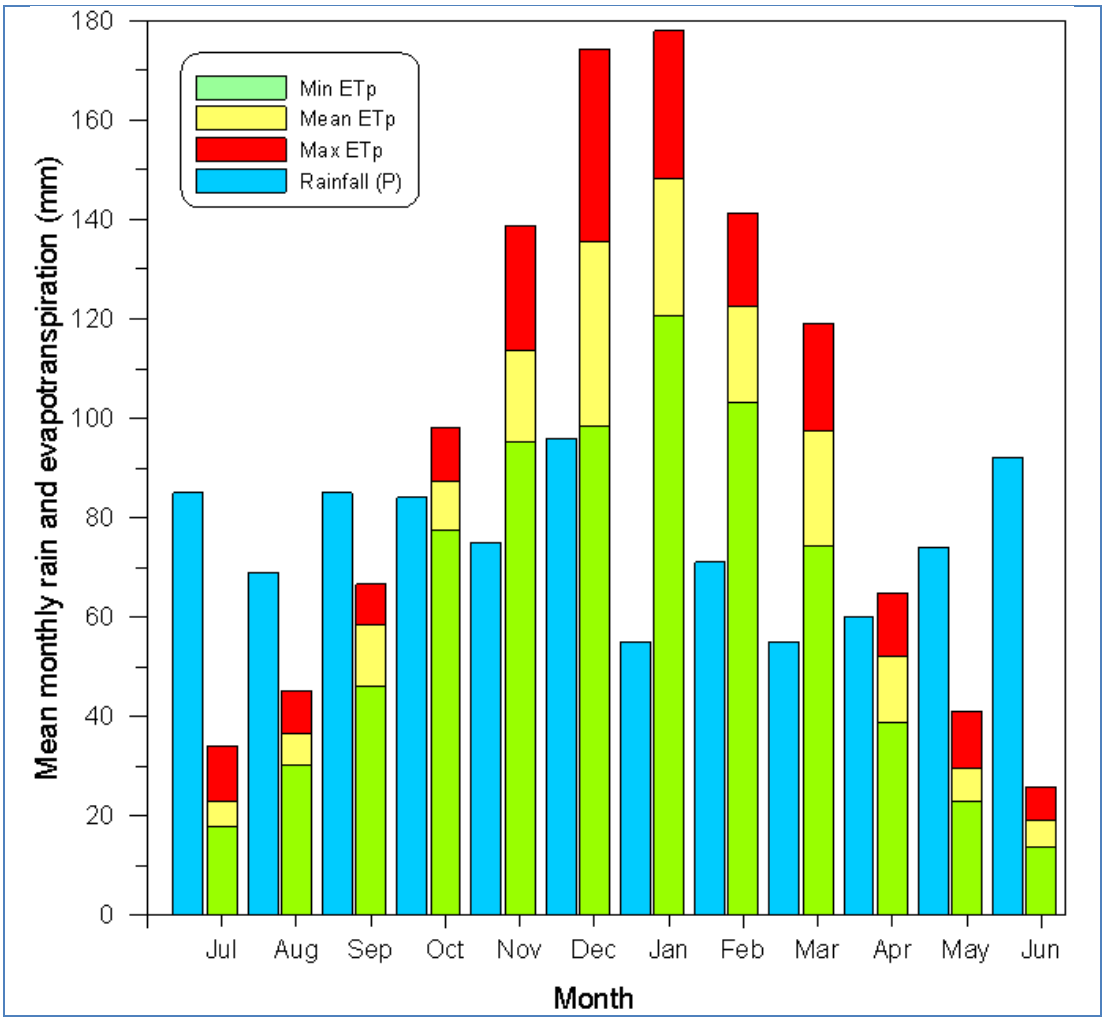

Figure 4-12. Mean rainfall (P) compared to calculated maximum, mean and minimum monthly potential evapotranspiration (ET_p) at Palmerston North Aws station (data sourced from Chappell, 2015).

Differences between mean monthly rainfall data presented here and those presented in the inset in Figure 4-8 may be due to differences in the analysed periods.

4.6.4 Hydrological year

The graph in Figure 4-12 suggests that a hydrological year in the LMC can be defined from 1 July to 30 June. This agrees with the NIWA recommended water year for the North Island of New Zealand. The calendar year is not suitable for hydrological calculations because significant droughts often begin in December and extend over summer, which can lead to double counting of droughts (Henderson & Diettrich, 2007).

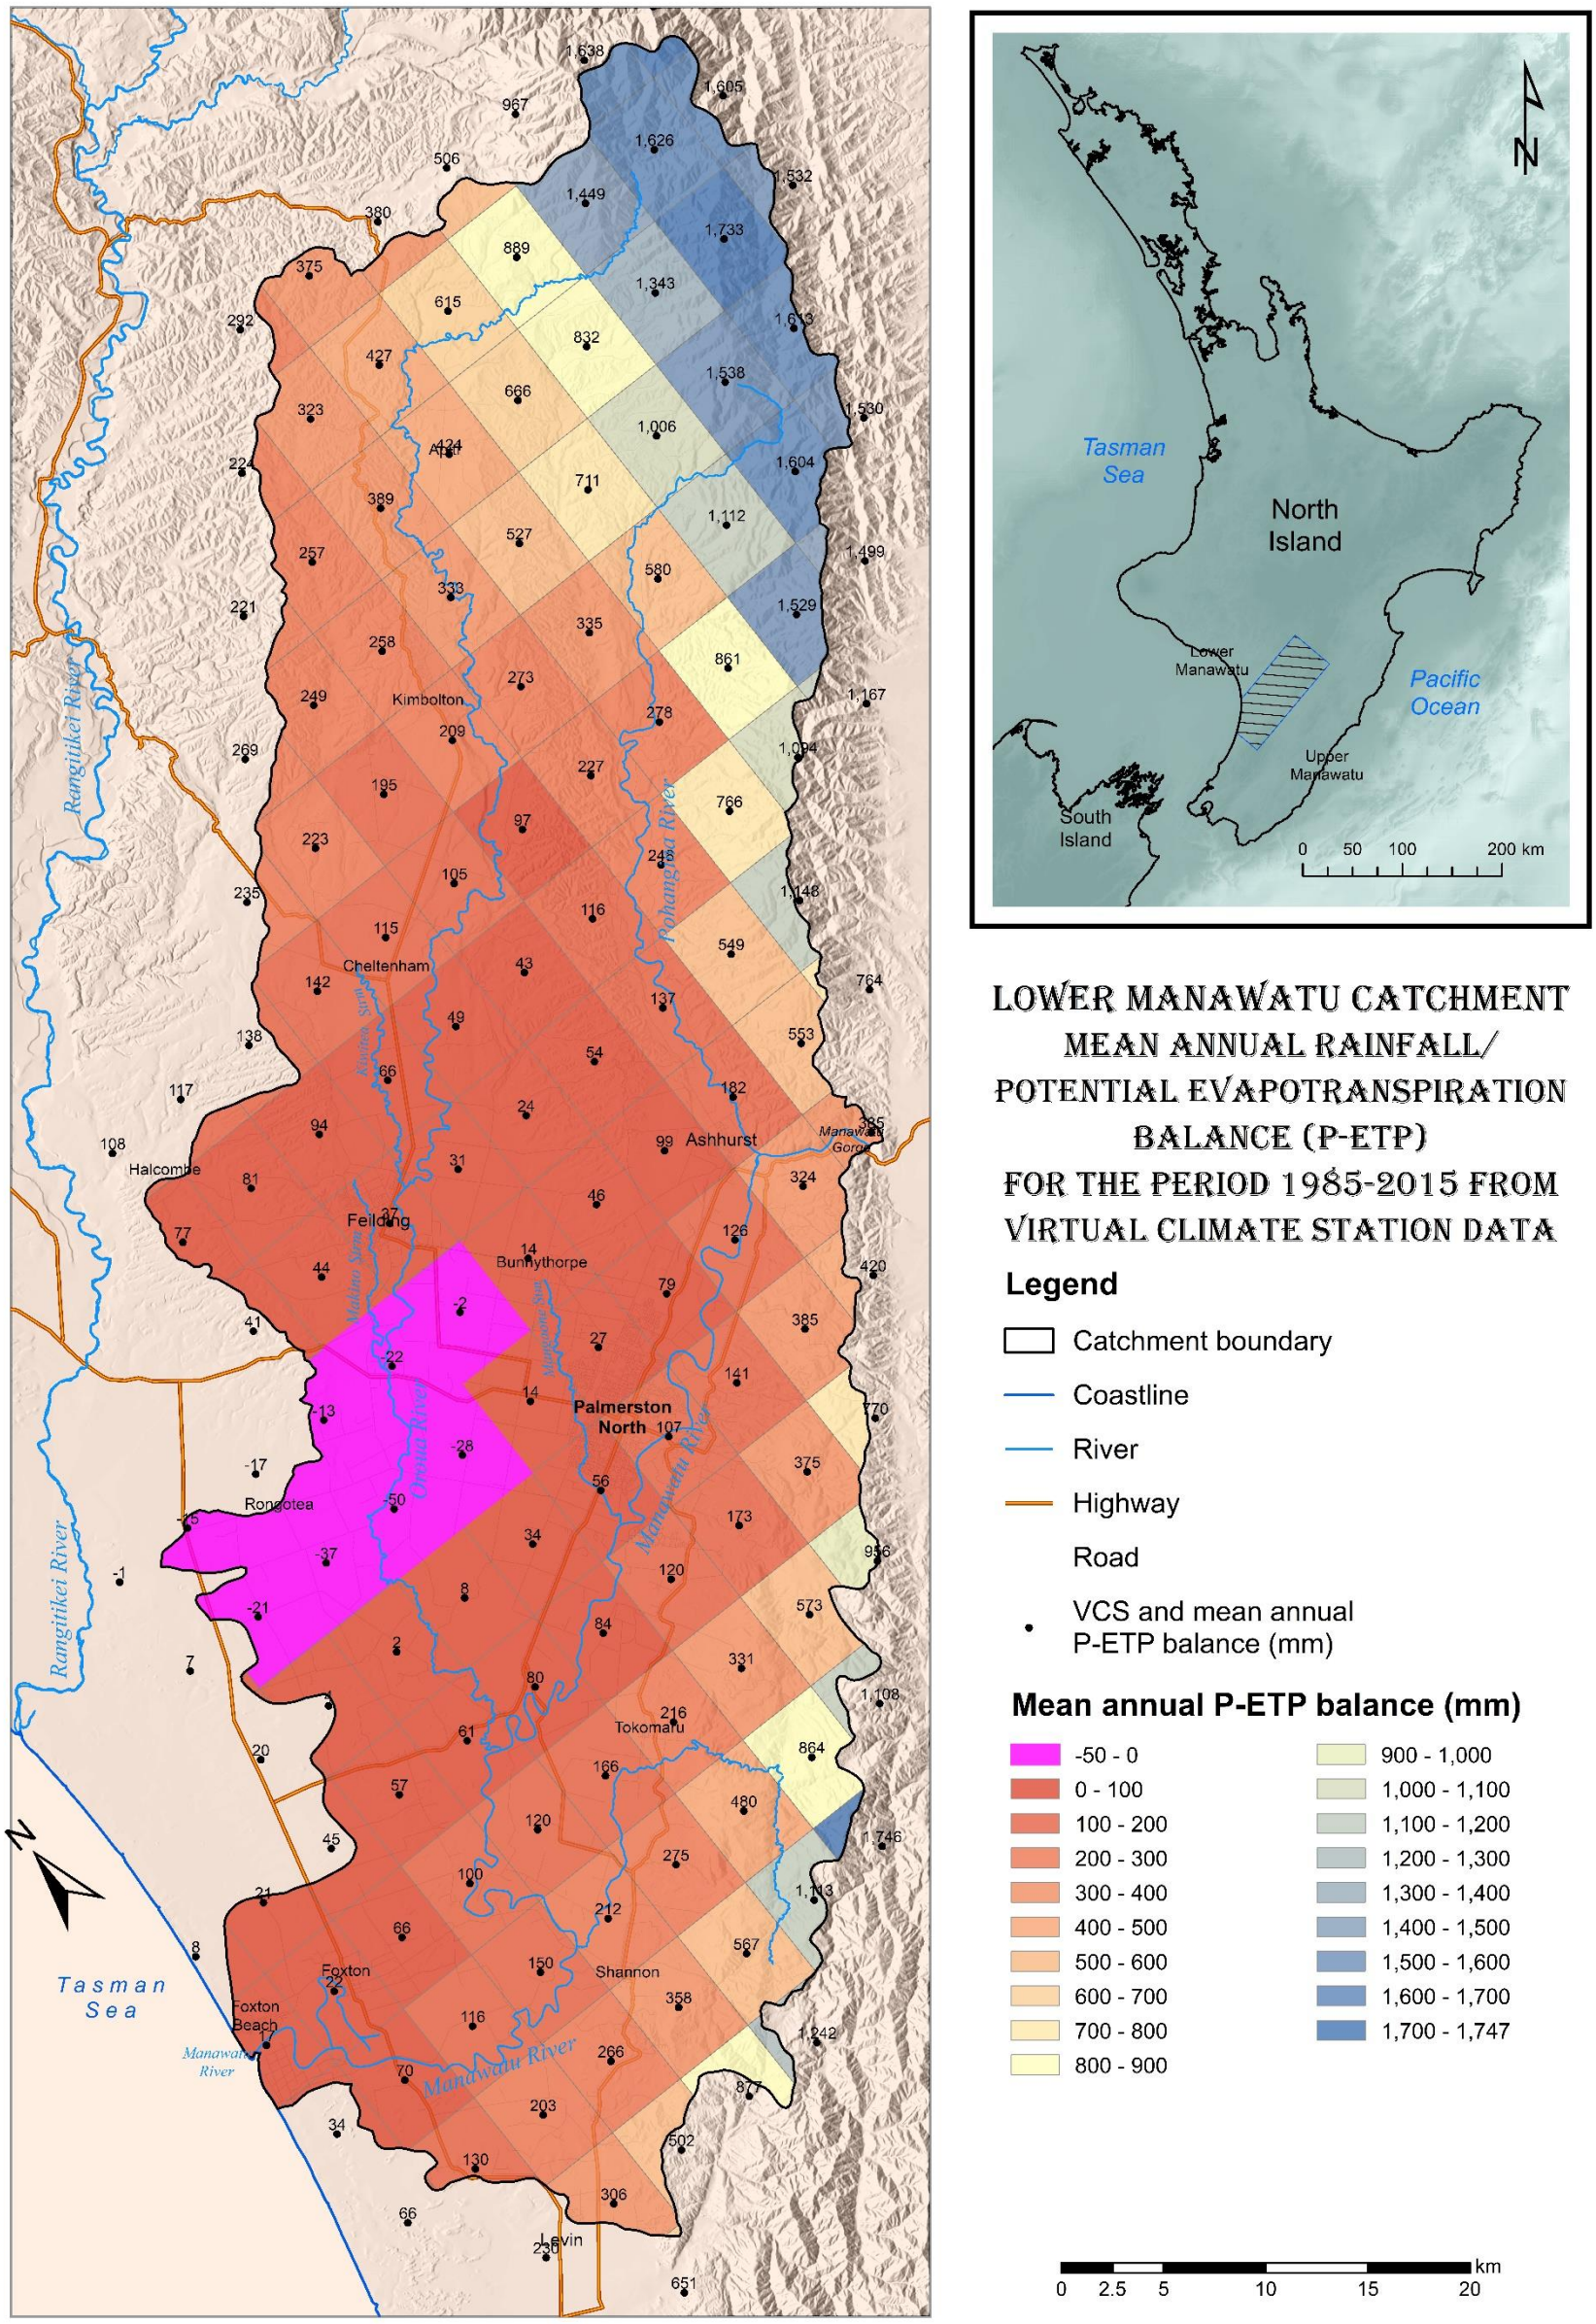

Figure 4-13. Mean annual difference between rainfall and potential evapotranspiration calculated from VCS data for the period 1985–2015.

4.7 LMC soil moisture balance modelling

4.7.1 Set up

A purpose-built Microsoft® Access™ 2016 application[29] (Figure 4-14) has been prepared using Visual Basic for Applications (VBA) to undertake SMB modelling for the LMC over the period 1/01/1985 – 31/12/2015.

The LMC SMB model utilises synthetic daily rain and evapotranspiration data from NIWA's VCS network. Thiessen polygons have been drawn to delineate the area represented by each VCS (Figure 4-5). Soil hydraulic properties have been set by classifying soil in the area according to the United States Department of Agriculture (USDA) Soil Texture Classification (STC) based on their Fundamental Soil Layer (FSL) classification (Table 4-6). To represent sealed areas, 'built-up area' and 'basement rock' soil types have been added to the USDA-STC. These areas have been delineated based on data from the geological map (Figure 3-16) and from the 2012 Ministry for the Environment (MfE) land use map (Figure 4-15). Unclassified soils in the FSL in the coastal area to the south of the Manawatu River have been typified as sand in the USDA-STC. Unclassified soils in the FSL in the Tararua Range area were typified as silt loam in the USDA-STC. However, this later assumption may have no real bearing on the modelling results because much of the area covered unclassified soils in the Tararua Range has been considered basement rock area where only evapotranspiration and surface runoff can take place, rendering soil properties irrelevant to the calculations.

The 2012 Ministry for the Environment land use map (Figure 4-15) implies that most of the LMC excluding built-up and basement rock area is grassland with some cropland patches. This enables SMB modelling simplification whereby all soil-covered land can safely be considered grassland.

[29]

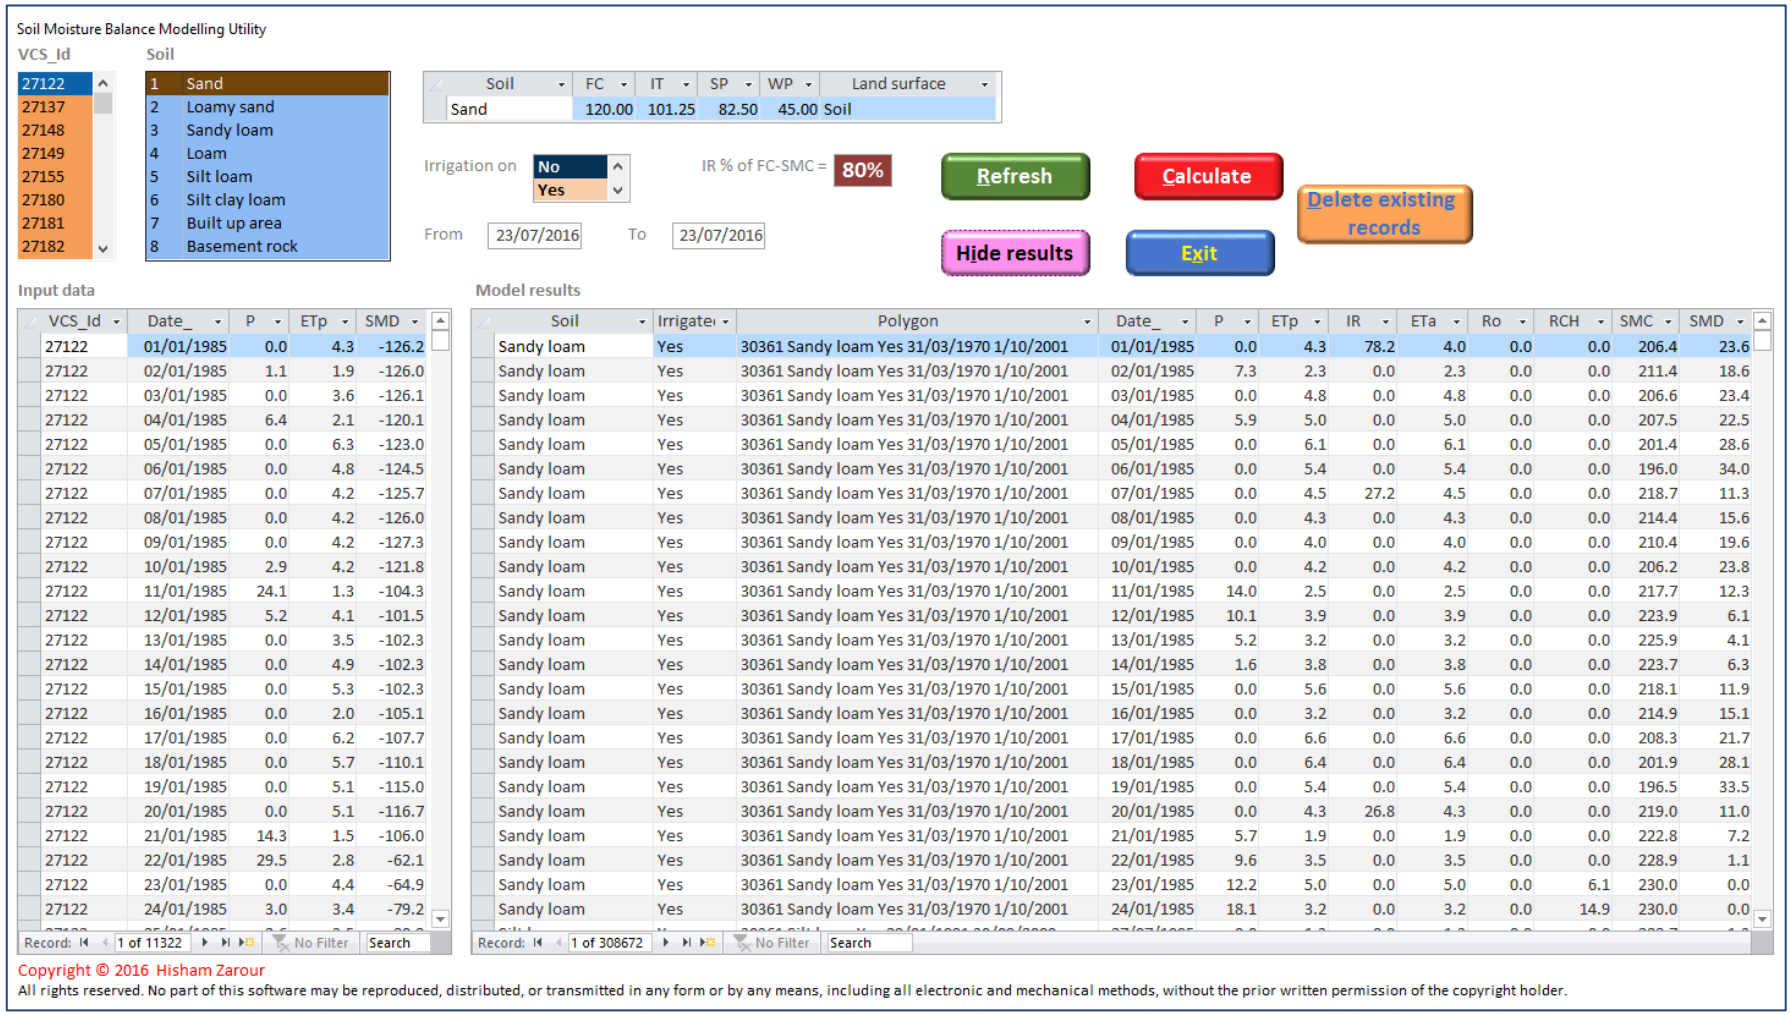

Figure 4-14. Screenshot of the user interface for the LMC SMB model.

Table 4-6. Typical soil water characteristics for various USDA-STC[30] classes (after Allen *et al.*, 1998), correlated to LMC soils based on NZ FSL.

USDA STC Soil type	New Zealand Fundamental Soil Layer Soil Type	Soil water characteristics (m^3/m^3)		
		θFC[31]	θWP	TAW[32]
Sand	Black sand, sand, sand & stony gravel, weakly mottled sand	0.07 – 0.17	0.02 – 0.07	0.05 – 0.11
Loamy sand	Brown loamy sand, loamy sand, loamy sand & sandy loam	0.11 – 0.19	0.03 – 0.10	0.06 – 0.12
Sandy loam	Black sandy loam, brown sandy loam, fine sandy loam, mottled fine sandy loam, mottled sandy loam, sandy loam, sandy loam and silt loam, stony loam	0.18 – 0.28	0.06 – 0.16	0.11 – 0.15
Loam	Loam	0.20 – 0.30	0.07 – 0.17	0.13 – 0.18
Silt loam	black silt loam, heavy silt loam, mottled silt loam, peaty silt loam, sandy loam and silt loam, silt loam, silt loam and clay loam, silt loam on sand, stony silt loam, strongly mottled silt loam	0.22 – 0.36	0.09 – 0.21	0.13 – 0.19
Silt clay loam	Loamy peat, peaty loam	0.30 – 0.37	0.17 – 0.24	0.13 – 0.18
Built-up area[33]	Town	—	—	—
Basement rock[33]	Rock	—	—	—

[31] θ: Content (%).
[32] $TAW = \theta FC - \theta WP$.
[33] Not in original USA-STC.

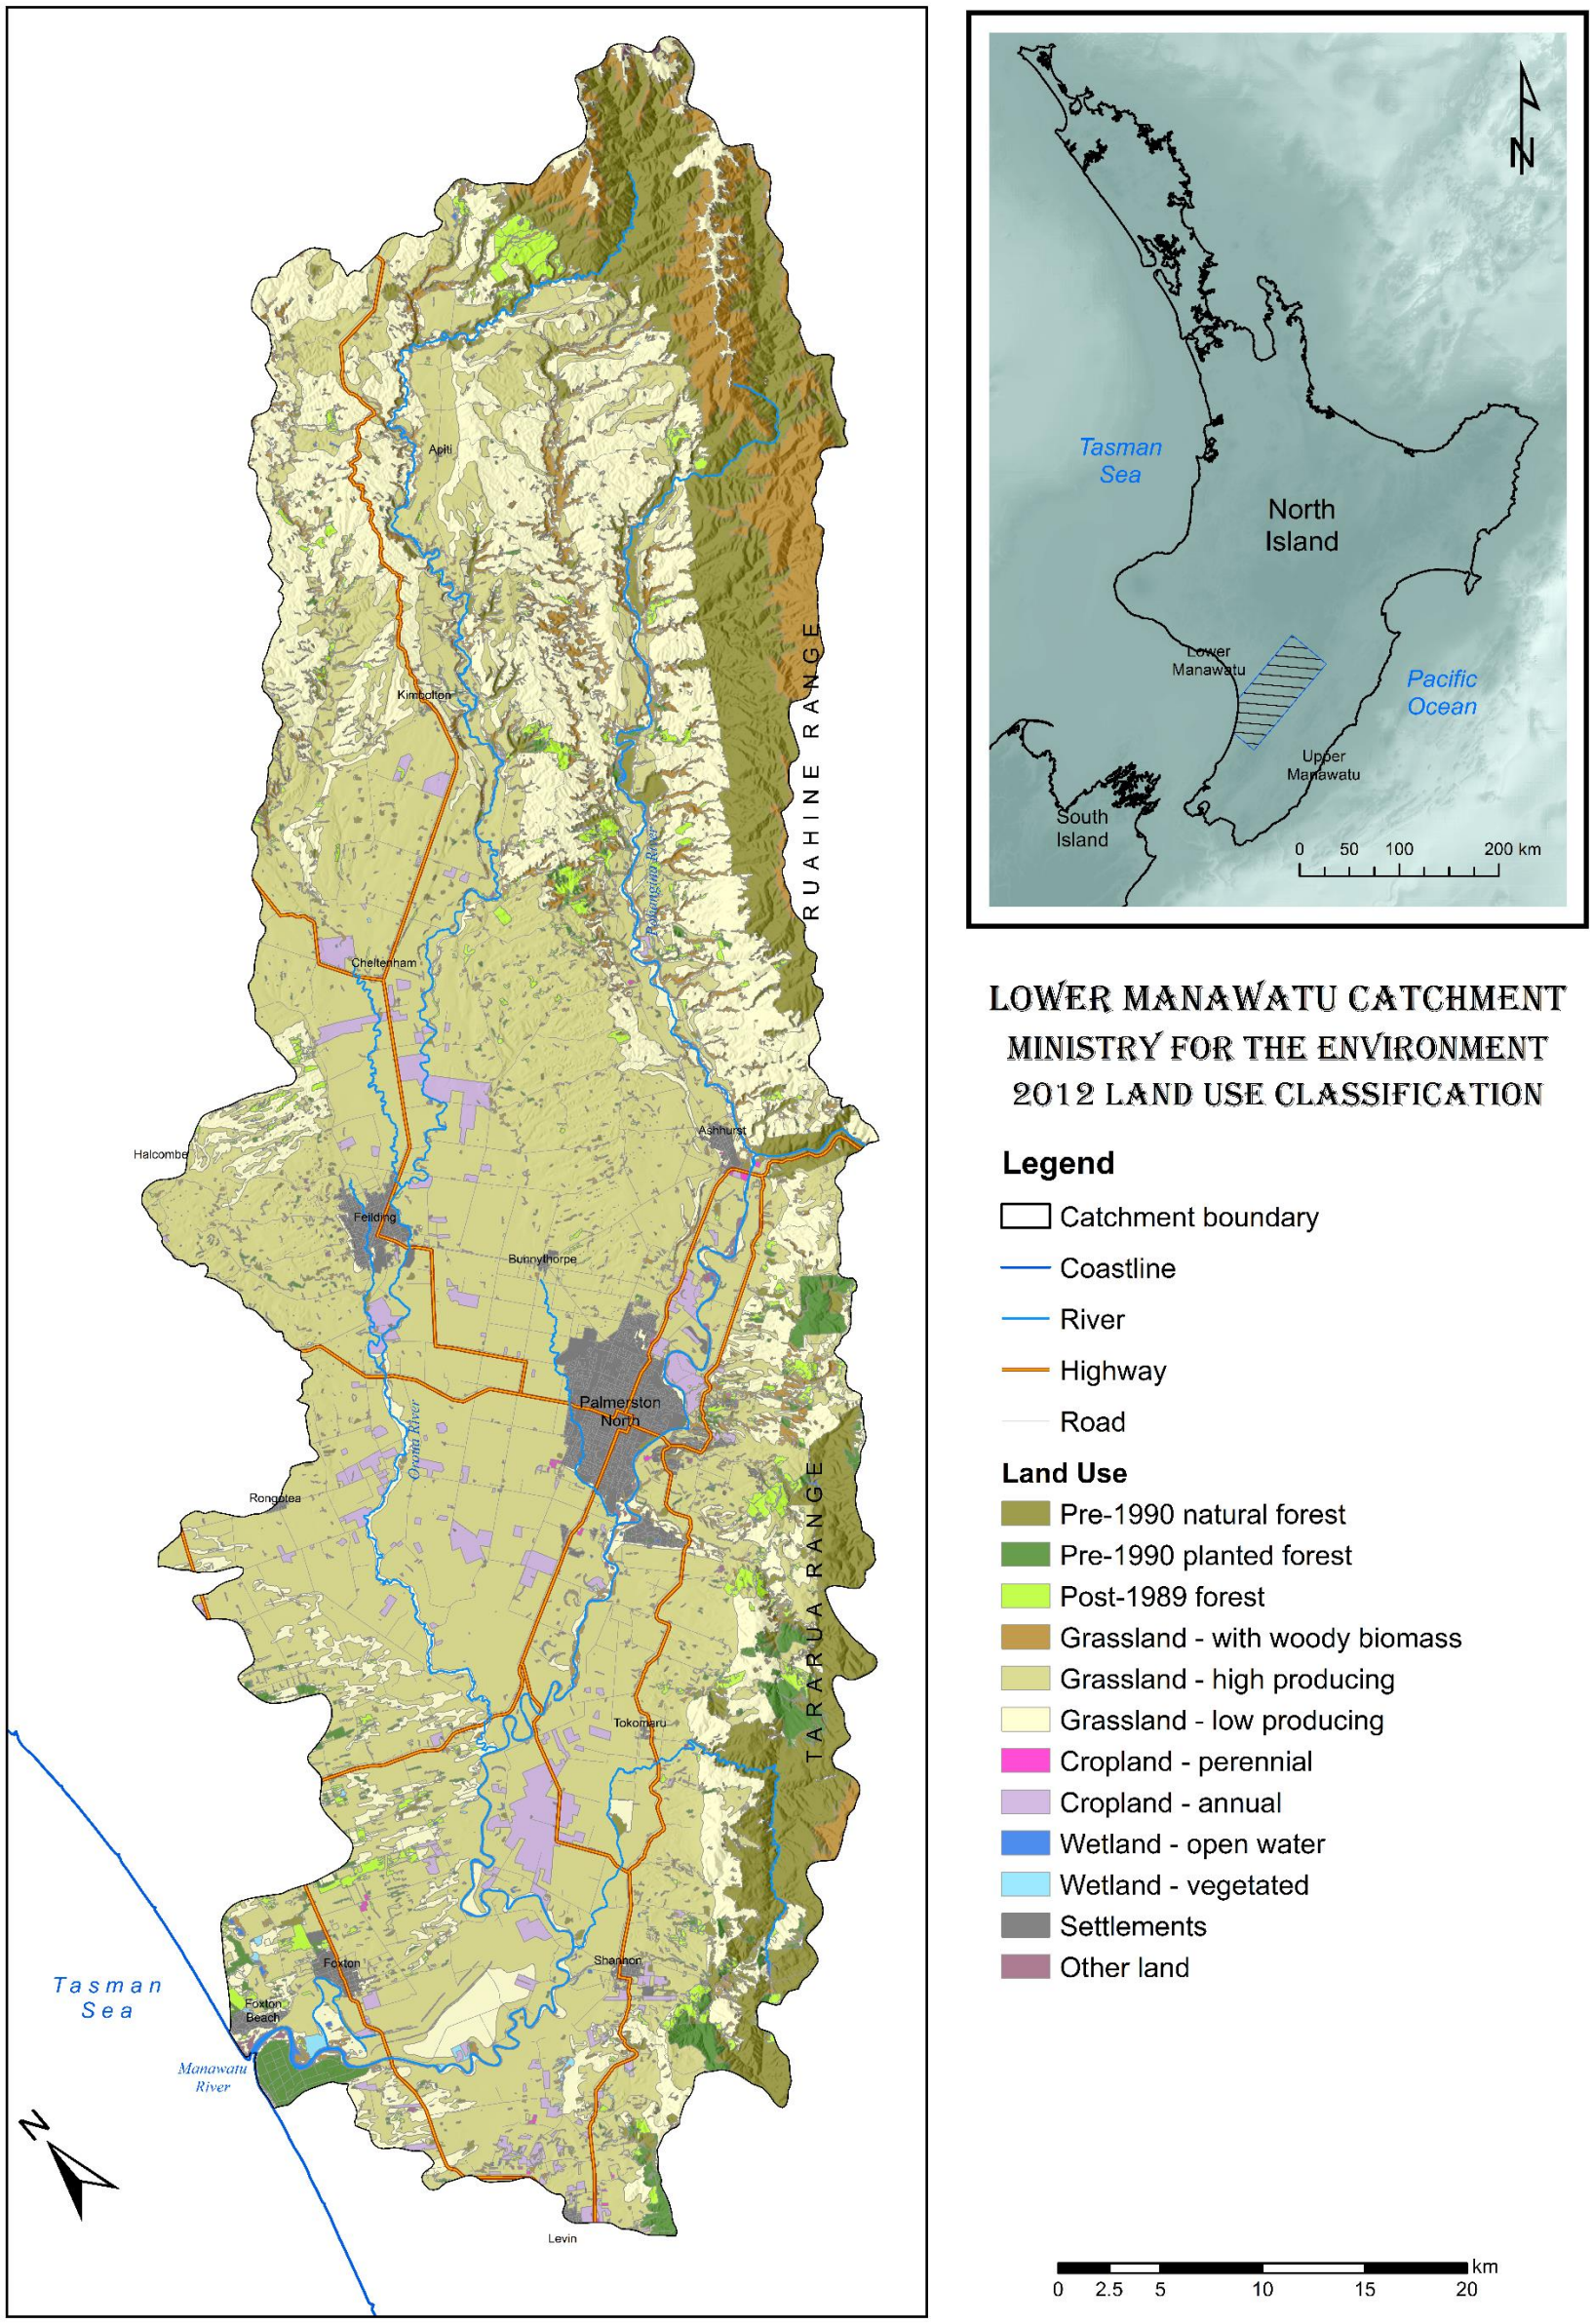

Figure 4-15. Ministry for the Environment 2012 land use map.

The LMC SMB model makes the following assumptions:

(1) Rainfall and irrigation are the only forms of precipitation, i.e. no snow or dew

(2) Daily time step

(3) 1 m soil profile

(4) Grass grown everywhere except in built-up and basement rock areas, i.e. $K_c = 1$

(5) Irrigation is only practiced with a resource consent and only over the term of the consent (data sourced from Horizons consents database to identify irrigated areas)

(6) Irrigation is only practiced during the irrigation season (October–March, inclusive)

(7) Water is available for irrigation where and when needed

(8) If SMC at the beginning of the day is below the midpoint between FC and SP, irrigation is applied to replenish soil moisture to 80% of PAW

(9) Water input into the soil is limited to P and IR, i.e. there is no upward or lateral seepage

(10) Water available to meet ET_a on any day include initial SMC, P and IR

(11) Evapotranspiration demand is met as follows

   i. In built-up and basement rock areas, the smallest of P and ET_p

   ii. Elsewhere, ET_a is achieved at full potential where $SMC \geq SP$ and at reduced rate ranging from 100% at $\mathrm{SMC} = SP$ to 0% where $SMC \leq WP$

(12) After ET_a, R_O occurs when $SMC > 100\%$, i.e. soil is saturated

(13) RCH does not take place in built-up and basement rock areas

(14) After ET_a and R_O, RCH occurs while $SMC > FC$

(15) RCH can drain freely into a permeable subsurface medium (e.g. aquifer)

(16) R_O does not turn into RCH

(17) End of day SMC is calculated as the balance of all input and output terms in Eq. 4-1

(18) End of day SMC is carried over to the following day as initial SMC.

To account for spatial variability in the LMC SMB model, the area was divided into 1,686 polygons by overlaying GIS polygon layers representing VCS Thiessen polygons, soil types, farming practices (irrigated or dry land farming), and terms of irrigation consents where applicable. For each resultant polygon, the LMC SMB model calculated daily values of P, ET_p, IR, ET_a, R_O and RCH as depth in mm.

Corresponding volumes were calculated by multiplying depths by polygon areas. Mean annual volumes over the LMC three sub-catchments were thereafter summed and averaged (Table 4-7).

4.7.2 Results

The LMC SMB model indicates that ET_p demand is least met in the built-up and basement rock area (Figure 4-16). This is understandable because the model assumes no soil moisture storage capacity in these two land categories, which means water is available to fully or partially meet ET_p demand only on rainy days.

Figure 4-17 and Figure 4-18 show the model calculated long-term mean annual R_O mean annual RCH, respectively. The LMC SMB model estimates the long-term mean annual recharge to be 23.43% of precipitation (Table 4-8). This is noticeably agreeable with the estimation of 22.43% by Zarour (2008).

A SMB model scenario was also run assuming no irrigation in the area (Table 4-9). On catchment-wide scale, the differences in SMB modelling results with and without irrigation are negligible.

Table 4-7. SMB model calculated mean annual rain, potential evapotranspiration, irrigation, actual evapotranspiration, surface runoff and groundwater recharge over the periods 1985-2015.

Catchment	Area (m^2)	Units	P	ET_p	IR	ET_a	R_O	RCH

4.7.3 Limitations

Like all models, the SMB model presented in this chapter simplifies reality. In doing so, conceptual and computational approximations had to be made.

The LMC SMB model is focused on assessing direct groundwater recharge from atmospheric precipitation. It also estimates actual evapotranspiration, reference crop irrigation demand, surface water runoff, soil moisture content and soil moisture deficit. Recharge from urban runoff and losses from water and wastewater networks and storage facilities is out of scope for this specific component of the research. Notwithstanding, applied and academic research shows that urbanisation affects groundwater recharge from precipitation, distorting its natural areal distribution, timing and rates (Barrett *et al.*, 1997; Foster *et al.*, 2005; Hughes & Mansour, 2005; Lerner, 2000, 2002). However, urban water balance is a matter that is better dealt with separately from SMB modelling. Direct recharge from precipitation is only one aspect of urban hydrology and SMB modelling can be useful in dealing with it.

Urban recharge has not been included in the LMC numerical models presented in Chapter 8, which is a limitation discussed there. Since the study area is largely unurbanised, the effect of considering the built-up areas to be totally sealed to groundwater recharge in the LMC SMB model could be insignificant to the groundwater flow models presented in this thesis. In numerical groundwater flow models, adjusting hydraulic conductivity values in underlying model cells can compensate for errors in groundwater recharge estimates. It may be argued that this can result in unrealistic estimation of both groundwater recharge and hydraulic conductivity, but they both can be maintained within realistic bounds and the overall model would continue to reasonably represent the modelled system.

This research is focused on groundwater. So, the effects of assuming that the built-up areas are completely impervious and do not allow the infiltration of precipitation water on the LMC SMB model estimates of surface runoff have not been investigated. Estimation errors in surface water flows and stage elevations

are thought to be negligible in regional-scale, steady-state groundwater assessments and flow models.

The LMC SMB model does not incorporate lateral or preferential soil moisture flow or the possibility of flow interception. Lateral and preferential soil water flows and interception occur at the grid- and subgrid- scales. They are thought to be marginal in regional or catchment-scale water models and, hence, could be ignored without greatly affecting the reliability of the modelling outcomes (Section 4.2).

The above noted limitations of the SMB modelling exercise undertaken in this research must be acknowledged and are recommended to be considered in subsequent work. There is also scope to enhance the LMC SMB model through the incorporation of flow interception and lateral and preferential soil moisture flow components, which will particularly be useful in more site-specific and/or transient assessments and modelling work. The sensitivity of regional-scale SMB and numerical groundwater flow model solutions to assumptions relating to lateral, preferential and intercepted soil water flow is an area that merits further research.

4.7.4 Verification

The methodology adopted for SMB modelling in the LMC is consistent with research in New Zealand (e.g. Scott, 2004; Wilson & Lu, 2011; Woodward *et al.*, 2010) and internationally (e.g. Allen *et al.*, 1998; Dastane, 1978; de Silva & Rushton, 2007; Jensen *et al.*, 1997; Rushton *et al.*, 2006). The model-calculated actual evapotranspiration, irrigation demand and groundwater recharge values have been limitedly verified through comparison with previous work (e.g. Bekesi, 1998; Bekesi & McConchie, 1999; Zarour, 2008). The average results of the model are in general agreement with estimates reported in previous work, particularly with regards to the LMC SMB evapotranspiration estimates as compared to the results of the irrigation component of the Soil Plant Atmosphere System Model (SPASMO-IR) described in Green *et al.* (2004), White *et al.* (2010) and Green (2011).

The LMC SMB model-calculated surface water runoff values have not been validated against previous work or monitoring records. However, it can be said that the above noted basic verification of the other calculated parameters, namely, evapotranspiration and groundwater recharge, provides enough confidence that the model runoff estimates are overall reasonable.

Additional verification leading to possible enhancement of the model is recommended for future research. This can include calibration of the model against surface runoff measurements both on large and small-scales, calibration against actual measurements of soil moisture and water deep percolation, and comparison with outputs of other methods and software packages.

Chapter 5 Hydrology

5.1 Introduction

Groundwater and surface water are a single resource (e.g. White *et al.*, 2001; Winter *et al.*, 1998). Therefore, hydrogeological investigations and modelling must account for surface water bodies that interact with the investigated groundwater resource.

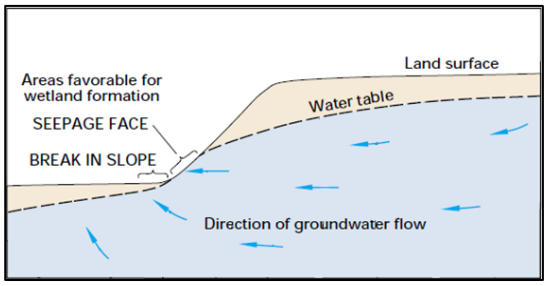
The interaction between groundwater and surface water can take different forms, change in time and from one place to another. Figure 5-1 shows possible relationships between groundwater and stagnant surface water bodies such as lakes and wetlands. Figure 5-2 illustrates possible relationships between groundwater and running surface waterways like rivers and streams. Figure 5-3 presents a method for determining stream-groundwater relationship using groundwater level contour maps.

Groundwater abstraction affects natural groundwater-surface water hydraulic balance. It can result in depleting surface water by pulling water from it through the tapped aquifer or by intercepting groundwater that otherwise would had flowed into the connected surface water body.

5.2 Springs, seeps, lakes and wetlands

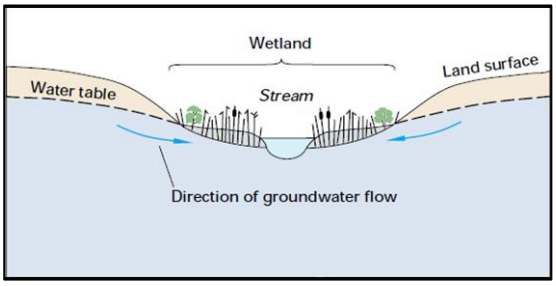
There are seeps in the LMC, but they are not mapped and there are no distinct springs. The area contains a few small lakes and wetlands (Figure 5-4). Nevertheless, none is particularly important from a hydrological perspective. Where directly connected to groundwater, such features can help with water table mapping, hydrogeological conceptualisation and numerical model set up and calibration.

Wetlands



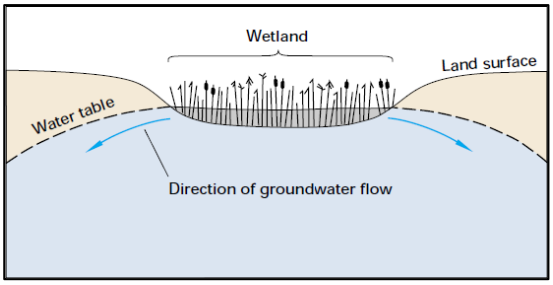
(a) Fens

Fens are wetlands that commonly receive groundwater discharge; therefore, they receive a continuous supply of chemical constituents dissolved in the groundwater.



(b) Riverine wetlands

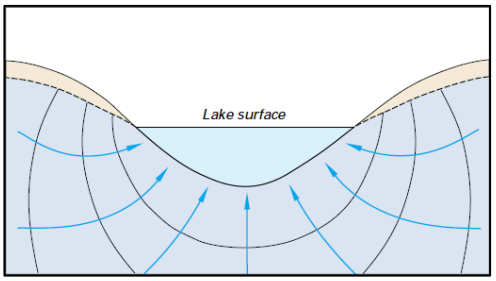
Many wetlands are present along streams, especially slow-moving streams. Although these riverine wetlands commonly receive groundwater discharge, they are dependent primarily on the stream for their water supply.



(c) Bogs

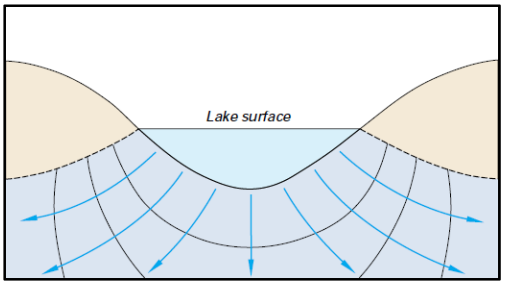
Bogs are wetlands that occupy uplands or extensive flat areas. They receive much of their water and chemical constituents from precipitation. They have the potential to affect groundwater quality.

Lakes



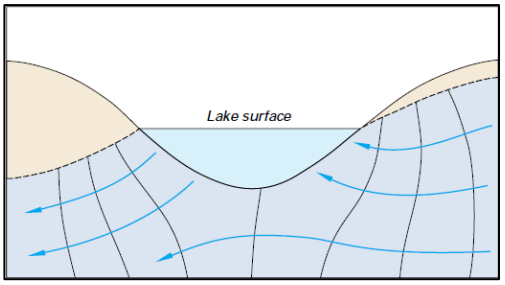
(d) Gaining lake

Groundwater level is higher than the lake water level. Hence, water moves from the aquifer into the lake.



(e) Losing lake

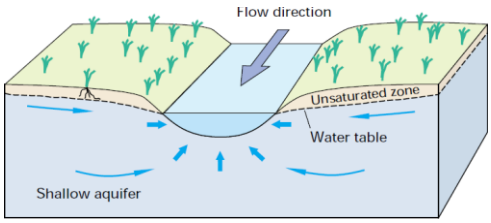
Groundwater level is lower than the lake water level. Hence, water moves from the lake into the aquifer.



(f) Groundwater flow through lake

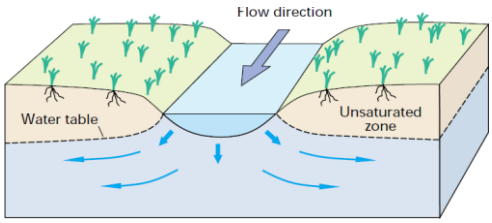
Groundwater level is higher than the lake water level in one side and lower in the other side. Hence, part of the groundwater moves in the aquifer from one side to the other through the lake.

Figure 5-1. Possible relationships between groundwater, wetlands and lakes (after Winter *et al.*, 1998).



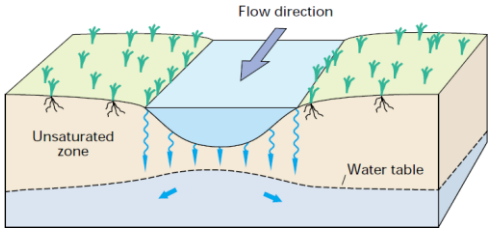
(a) Gaining stream

Gaining streams receive water from the groundwater system.



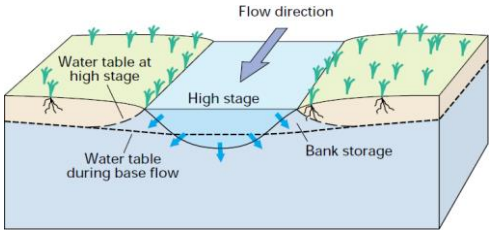
(b) Losing stream

Losing streams lose water to the groundwater system.



(c) Disconnected stream

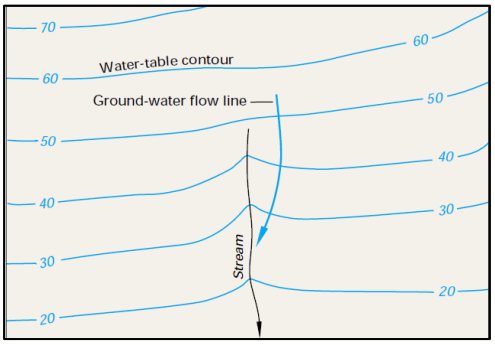
Disconnected streams are separated from the groundwater system by an unsaturated zone.



(d) Stream bank storage

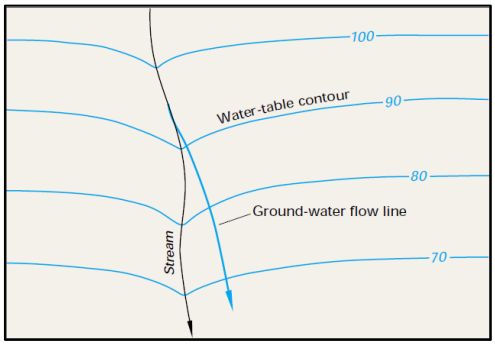
If stream levels rise higher than adjacent groundwater levels, stream water moves into the stream banks as bank storage.

Figure 5-2. Possible relationships between groundwater, rivers and streams (after Winter *et al.*, 1998).



(a) Gaining stream

Gaining streams (e.g. Figure 5-2a). The contour lines point in the upstream direction where they cross the stream.



(b) Losing stream

Losing streams (e.g. Figure 5-2b). The contour lines point in the downstream direction where they cross the stream.

Figure 5-3. Method for determining stream-groundwater relationship using groundwater level contour maps (after Winter *et al.*, 1998).

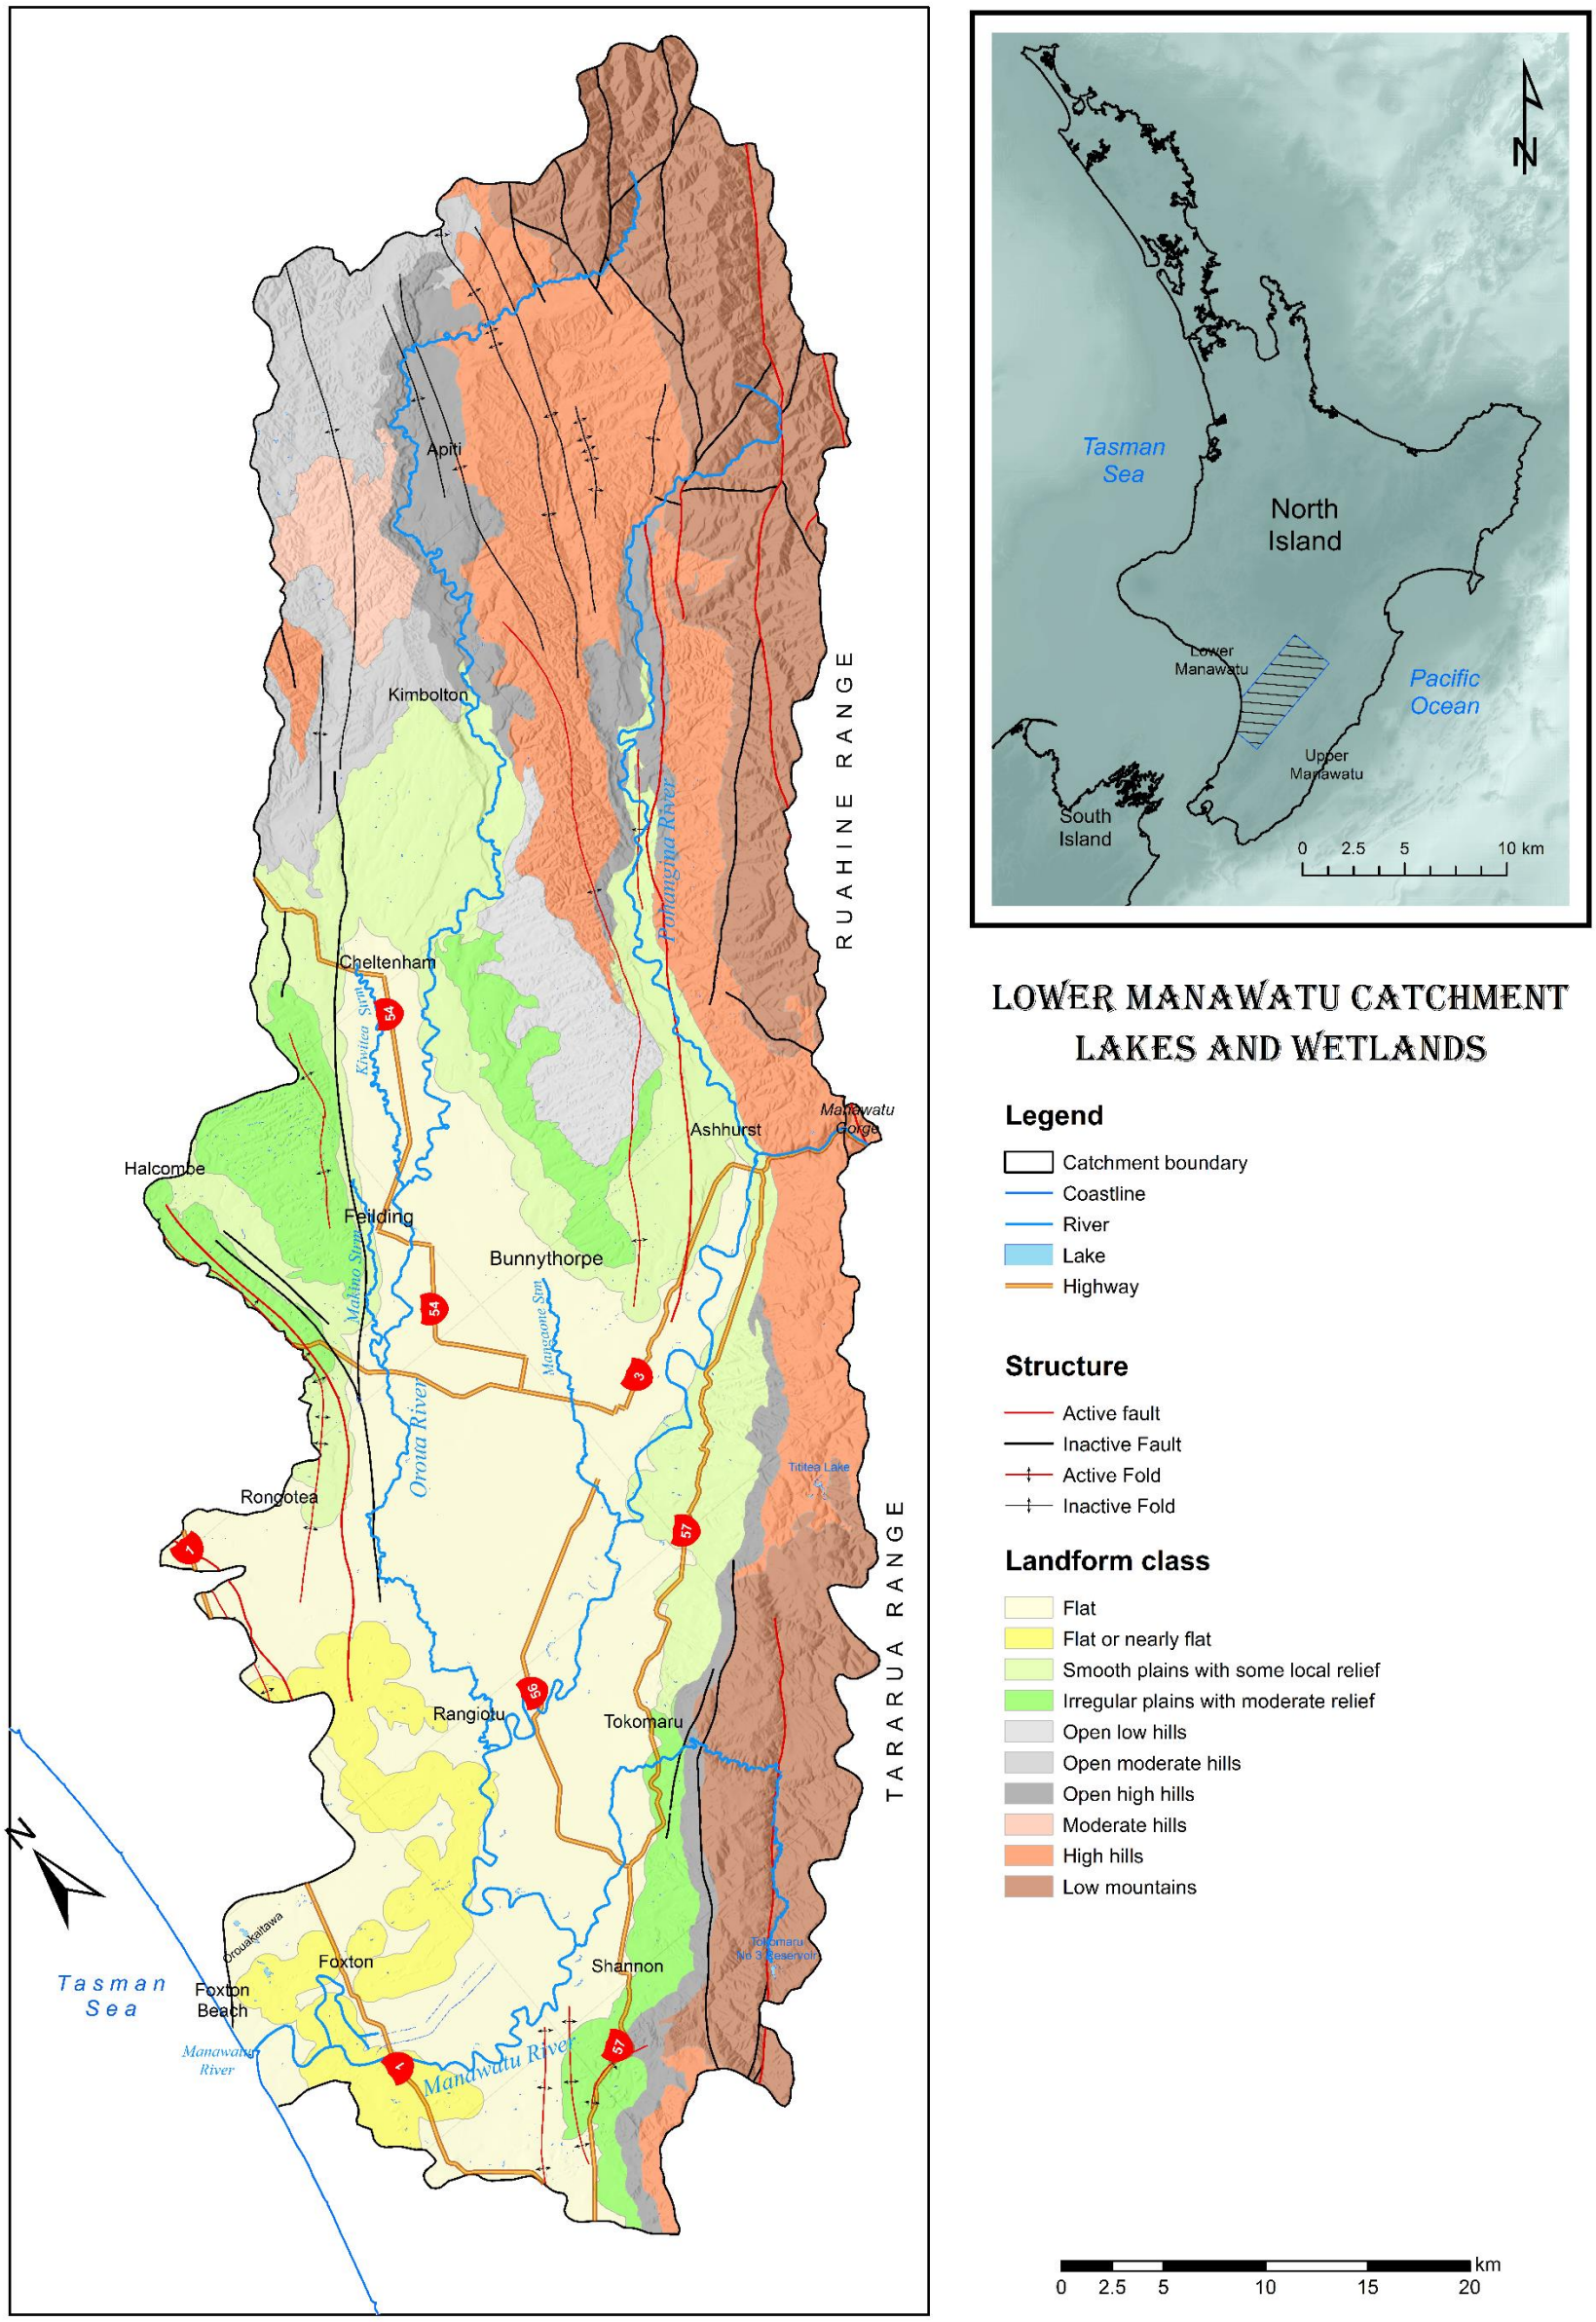


Figure 5-4. Lake distribution in relation to landforms and geological structure.

Lakes and wetlands in the LMC are small. Only 22 mapped lakes are larger than 2 ha in area. The dammed Turitea Lake is the largest in the LMC at about 11.5 ha. It is the main water source for Palmerston North. Tokomaru No 3 Reservoir (9.5 ha) is another relatively large dammed lake in the ranges. In the coastal area between Foxton Beach and Orouakaitawa, there is a north/south oriented line of relatively large wetlands/lakes (c. 5 – 10 ha) with smaller wetlands in between. The highest concentration of lakes coincides with anticlinal structures on the 'irregular plains with moderate relief' and to a lesser extent the 'smooth plains with some local relief' landforms identified in Section 3.9.4.

5.3 Rivers and streams

Figure 5-5 shows surface waterways in the LMC area that are in the order of 7 to 4 according to the New Zealand River Environment Classification (REC) system developed by the Ministry for the Environment. The REC system groups rivers of similar character across New Zealand according to factors such as climate, source of flow for the river water, topography, geology and catchment land cover.

5.4 Surface water monitoring and surveys

River flows monitoring in the study area started in the 1920s (Table 5-1). It has been carried out by Horizons Regional Council and its predecessors. In addition, flows and levels of some surface waterways in the LMC are monitored by NIWA and consent holders for compliance with their consent conditions (Roygard *et al.*, 2011). Figure 5-5 shows the monitoring sites in the area and Table 5-1 presents basic information and statistics for them.

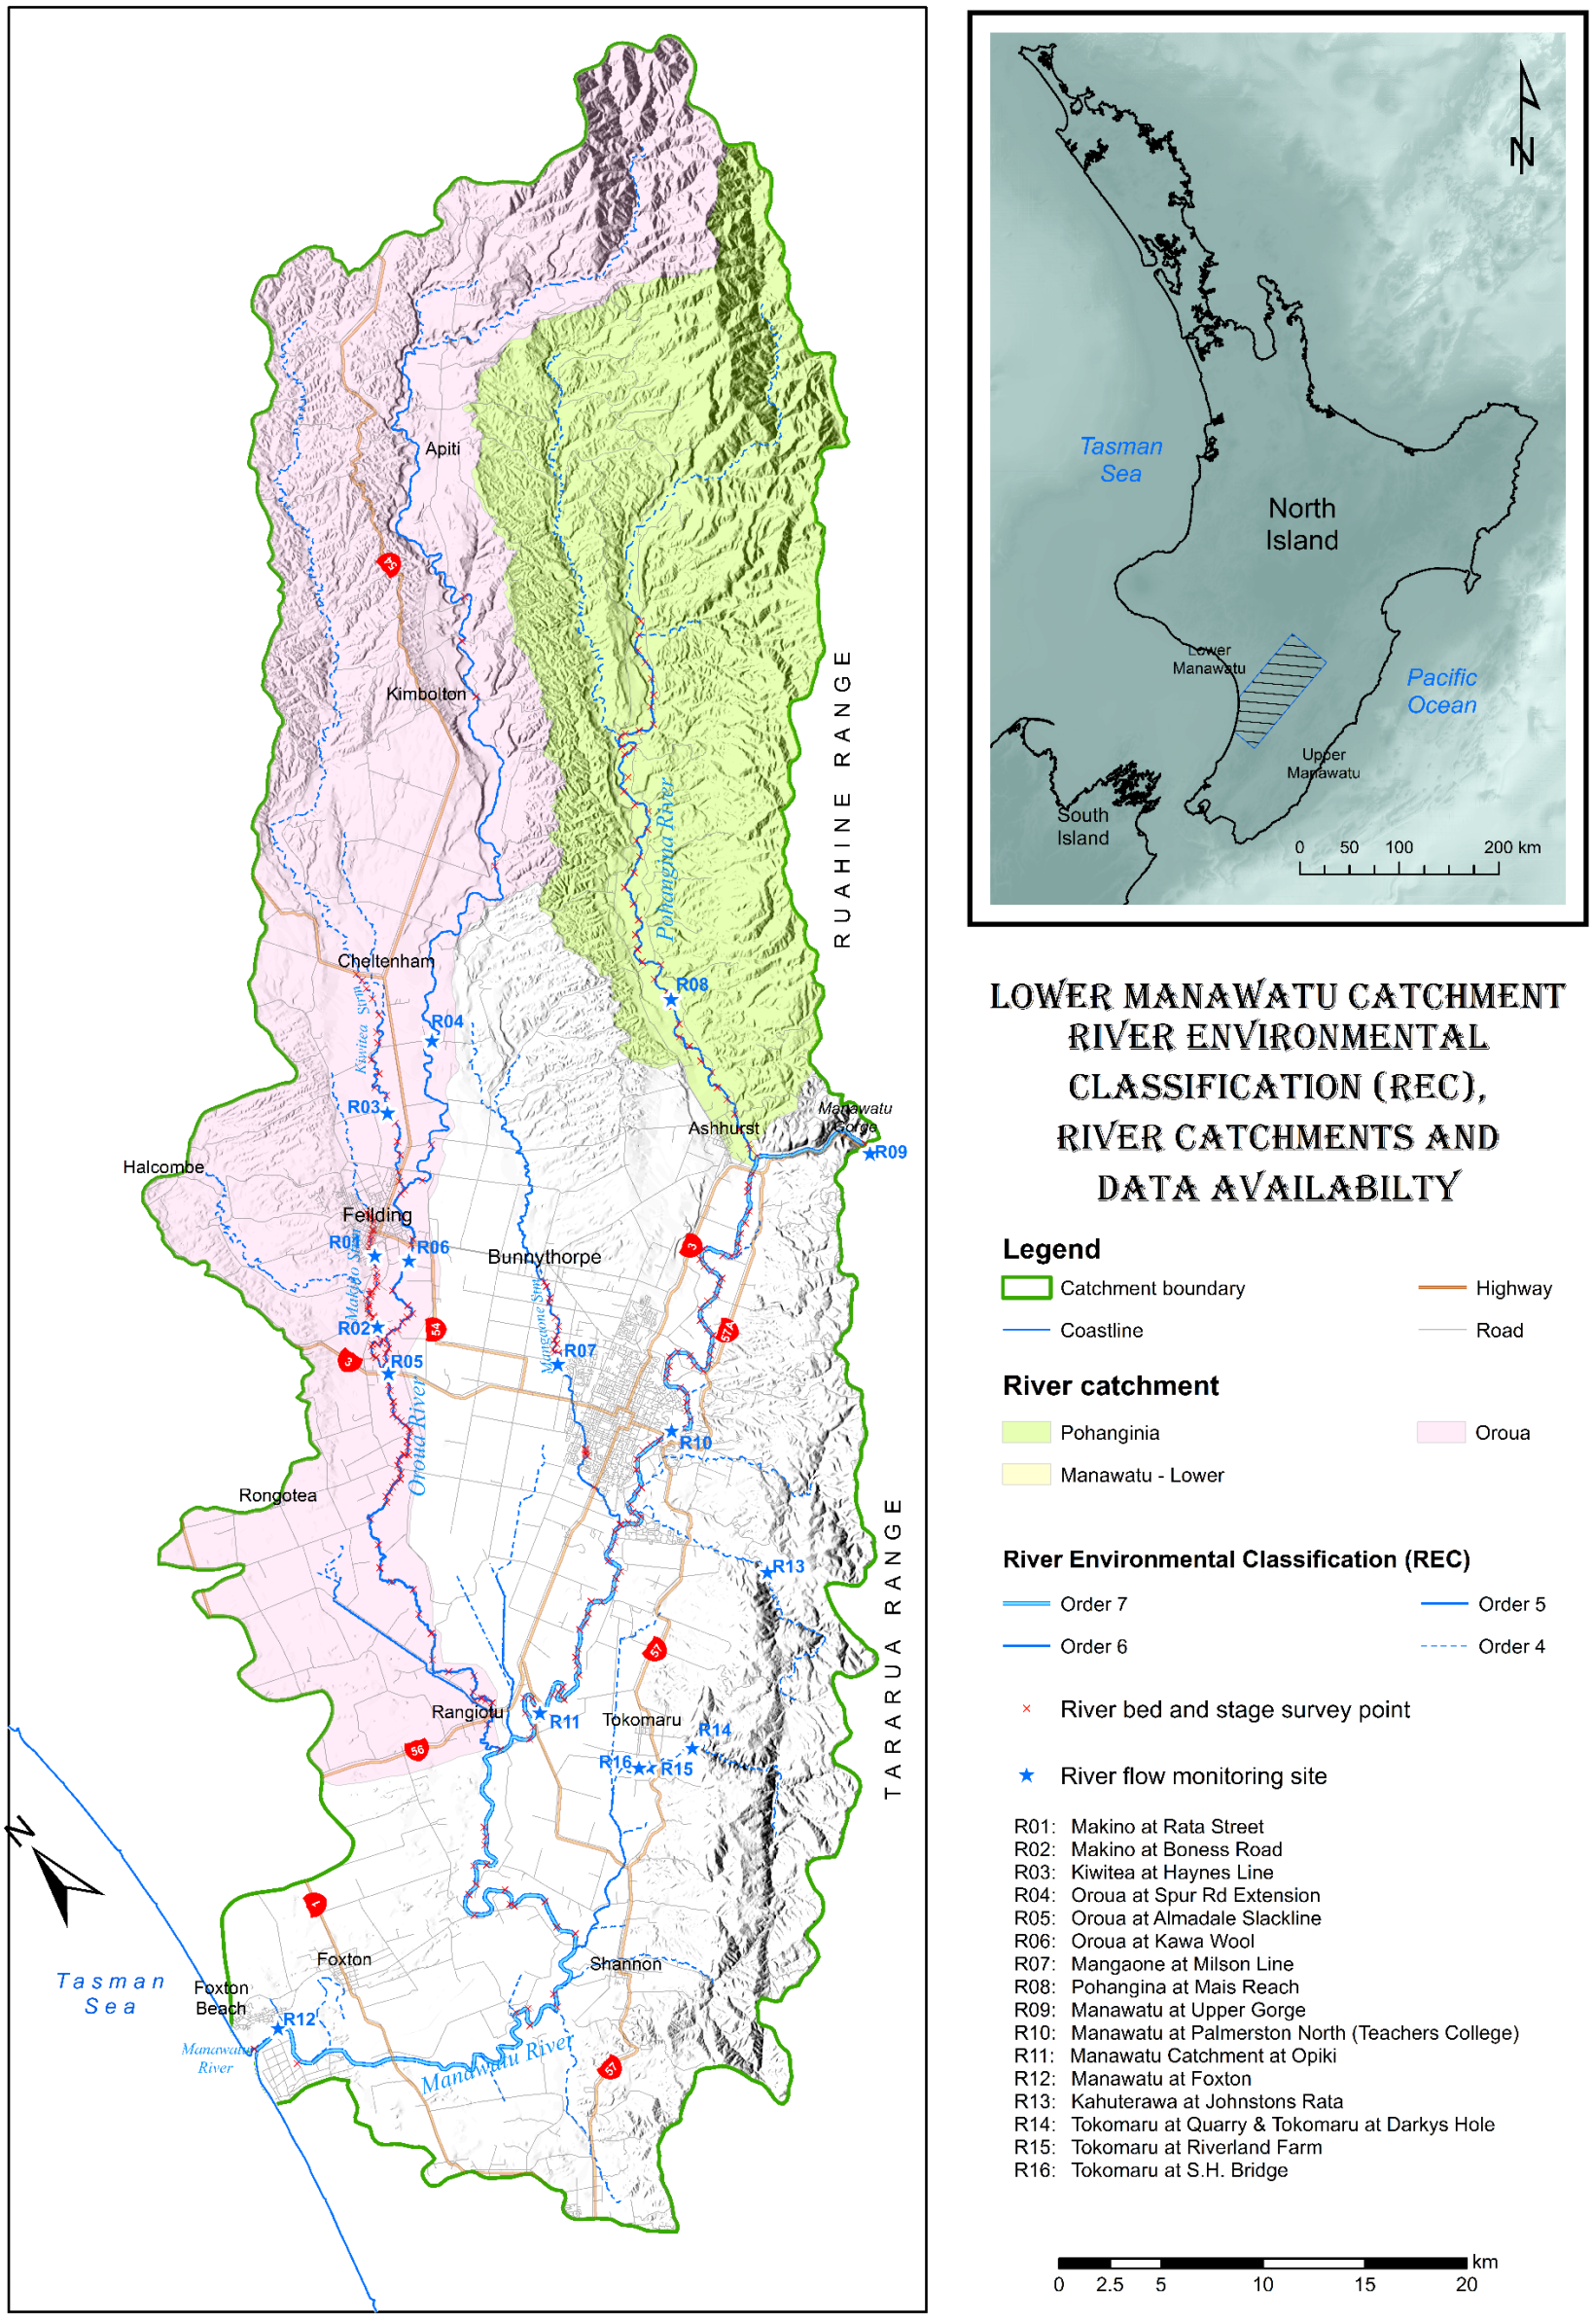

Figure 5-5. Environmental river classification (REC), river catchments and surface water data availability in the LMC.

Horizons Regional Council have also undertaken intermittent surveys of river bottom and stage elevation for main surface waterways in the LMC area over the period from 1/03/1990 to 21/12/2010 (Figure 5-5). The surveys have been undertaken in different seasons and under varying hydrometeorological conditions. Nevertheless, they can still be used to provide a general representation of the main surface waterways in the LMC for catchment-scale groundwater numerical modelling purposes.

5.5 Units and conventions

Commonly, surface water statistics are expressed in litres per second (L/s) or cubic metre per second (m^3/s or cumecs). Other units are also used to suit different purposes, e.g. Mega Litre per day (ML/day) are often used in water supply work and cumec-days (CMD) in the hydropower industry. In groundwater studies, however, units of metre (m), cubic metre (m^3) and million cubic metre (mcm) per day (d) or year (y) are conventional for flow, and millimetre (mm) or metre per day or year are common place to express parameters like recharge and groundwater level fluctuation, which are usually expressed as depth. For the purpose of comparison of river flow to other catchment wide variables such as rainfall, evapotranspiration and groundwater recharge, it is more convenient to use depth of runoff – the mean flow divided by the catchment area upstream of the flow recording site in mm/time interval unit.

Table 5-1. Continuous river level and flow monitoring sites operated by Horizons and basic flow statistics[34].

5.6 Hydrological statistics

Henderson and Diettrich (2007) documented flow statistics for Horizons and NIWA sites that have continuous flow records with an emphasis on low flow parameters. They note that flow measurements are commonly recorded at a short time interval of the order of 15 minutes. They consider that at least 10 year, preferably 20-year, long record is needed to allow the compilation of reliable flow statistics for a site comparison to other sites. They suggest that hydrological time-series can be initially defined by a short list of useful statistics that seeks defining the flow magnitude, its variability, and uncertainty. The various parameters in Henderson and Diettrich (2007) short list of flow statistics are described in Sections 5.7- 5.9.

5.7 General flow statistics

5.7.1 Mean flow

Mean flow is arguably the most important and commonly used statistical descriptor of river flow. Graphically, it is the area under the river flow hydrograph divided by the length of the hydrograph. Appendix B graphically presents yearly and monthly total and average flows for the sites noted in Figure 5-5 and Table 5-1 that have sufficient record.

In average, the LMC receives about 2,689 mcm/y of water from the upper catchment through the Manawatu Gorge and discharges about 3,859 mcm/y of water into the Tasman Sea (Table 5-1). Hence, the overall depth of runoff over the LMC area can be estimated to be c. 437 mm/y, compared to 315 mm/y as calculated from SMB modelling (Table 4-7). The difference between the two estimates (327 mcm/y **or** 122 mm/y) could be related to one or a combination of the following possibilities:

1. Failure to account for soil infiltration and storm characteristics in SMB calculations due to lack of data
2. Exaggerated soil thickness (1 m) assumed in SMB calculations (Section 4.7), resulting in underestimation of runoff (Table 4-7)

3. Overestimation of river discharge to the sea in the synthetic data for the Manawatu at Foxton site (Table 5-1)
4. Gauging inaccuracies in estimating flows at the Manawatu Gorge
5. Mean flows are calculated for different periods
6. Surface waterways gains from groundwater (Sections 5.9.2 and 5.12)
7. Unaccounted for effects of interflow in the LMC SMB model
8. Exclusion of drains from the water balance and numerical model calculations due to lack of data and perceived insignificance in regional-scale analysis.

Both surface runoff estimates represent unnormalised flow as they do not account for abstraction. Total surface water abstraction in the LMC (Section 5.11) is very small compared to the overall amounts of water in the catchment. Hence, surface water abstraction can be ignored in catchment-scale water budget calculations.

5.7.2 Median flow

Henderson and Diettrich (2007) define median flow as the flow that is equalled or exceeded half the time over the period of analysis. It is different from mean flow because river flow is not a normally distributed quantity. Henderson and Diettrich (2007) note that rivers in the area spend only about 30% of the time above the mean (standard deviation 5%), but these flows can be very large. Flows below the mean are bounded by zero as a lower limit.

5.8 Flow variability

The LMC is situated on the western side of the North Island, where variability is expected to be low relative to areas on the eastern side of the island (Henderson & Diettrich, 2007).

5.8.1 Yearly variability

Year to year variability in flow can be captured by use of annual average flows and their spread measured by a statistic such as standard deviation or coefficient of variation (standard deviation divided by the mean). Yearly flow variability at monitoring sites in the LMC can be noticed in the figures in Appendix B. Figure

5-6 presents flow variability percentiles for selected surface waterways as reported by Henderson and Diettrich (2007).

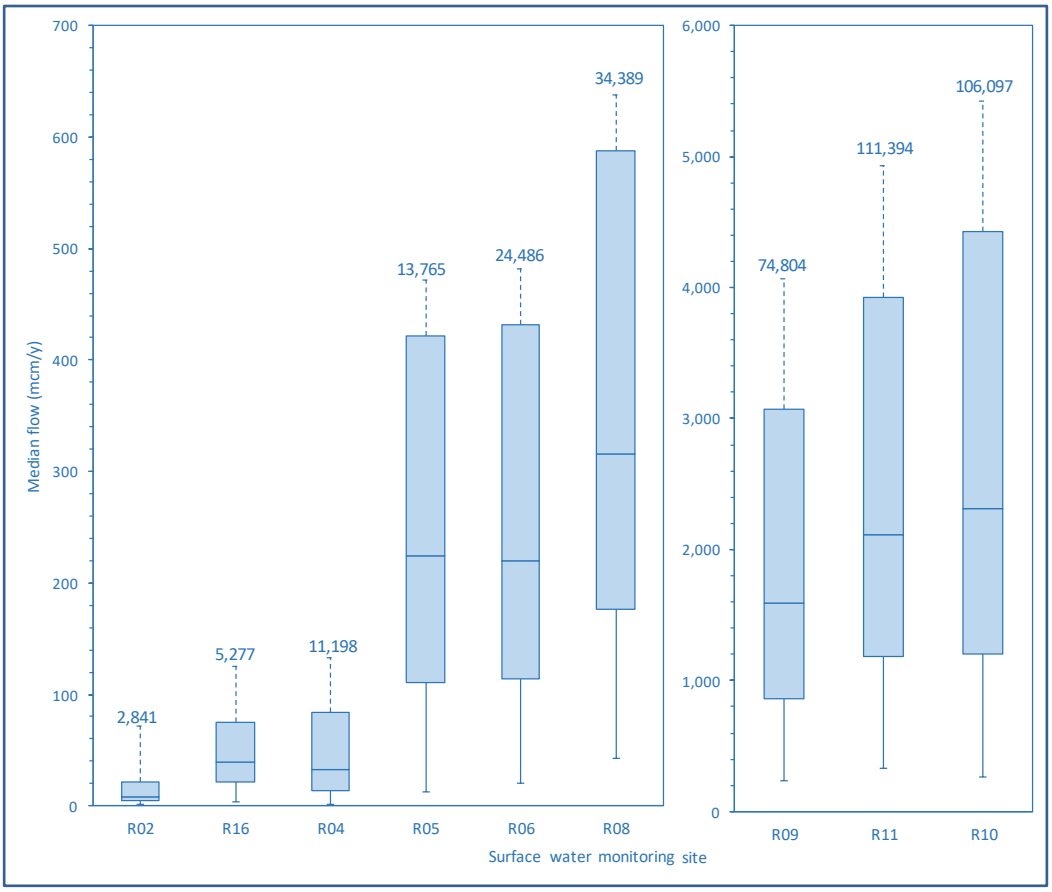

Figure 5-6. Flow variability percentiles for selected surface waterways (data from Henderson & Diettrich, 2007).

Surface water monitoring site locations are shown in Figure 5-5. Maximum flows are shown as numbers to enable showing other values in a reasonable scale. The low whisker extents show minimum flows. The tops and bottoms of the boxes represent the 75th and 25th percentiles, respectively. The lines in the middle of boxes represent medians

5.8.2 Seasonal variability

Graphical presentation of the distribution of monthly mean flows provides a measure of seasonal variability. Year to year variability of seasonal behaviour may be assessed by considering each month in turn, and calculating the quartiles, flow values that are equalled or exceeded one quarter and three quarters of the time (Henderson & Diettrich, 2007). Monthly flow variability at monitoring sites in the LMC can be noticed in the figures in Appendix B.

5.8.3 Flow distribution

Temporal flows distribution can be expressed as a range (maximum – minimum) or alternatively the inter-quartile range, which is less affected by extremes of floods and droughts. Flow distribution can also be used to examine seasonal flow variability on a monthly basis. A more detailed presentation of flow distribution is the flow duration curve (FDC). This curve plots each flow against the percentage of time that that flow is equalled or exceeded in the time period being analysed (e.g. Figure 5-7).

5.9 Flow extremes

High flows and low flows could be characterised in several ways; by the top and bottom 5%-10% of the FDC, by some multiple or fraction of the mean flow or median, or by use of extreme value sampling (low flows and floods).

5.9.1 Mean annual flood

Mean annual flood (MAF) is the average of the highest instantaneous flow measurement from each year. In New Zealand, the definition of a water year (Section 4.6.4) is generally not as important for floods as it is for the mean annual low flow calculations (Henderson & Diettrich, 2007). The magnitude of disturbance can be expressed as the ratio of MAF to mean and low flow. These ratios allow comparison between sites, and relate to the gradient of river environment from benign (low ratios) to harsh (high ratios). Mean annual flood values adopted in Table 5-1 from Henderson and Diettrich (2007) were calculated on a calendar year rather than a water year.

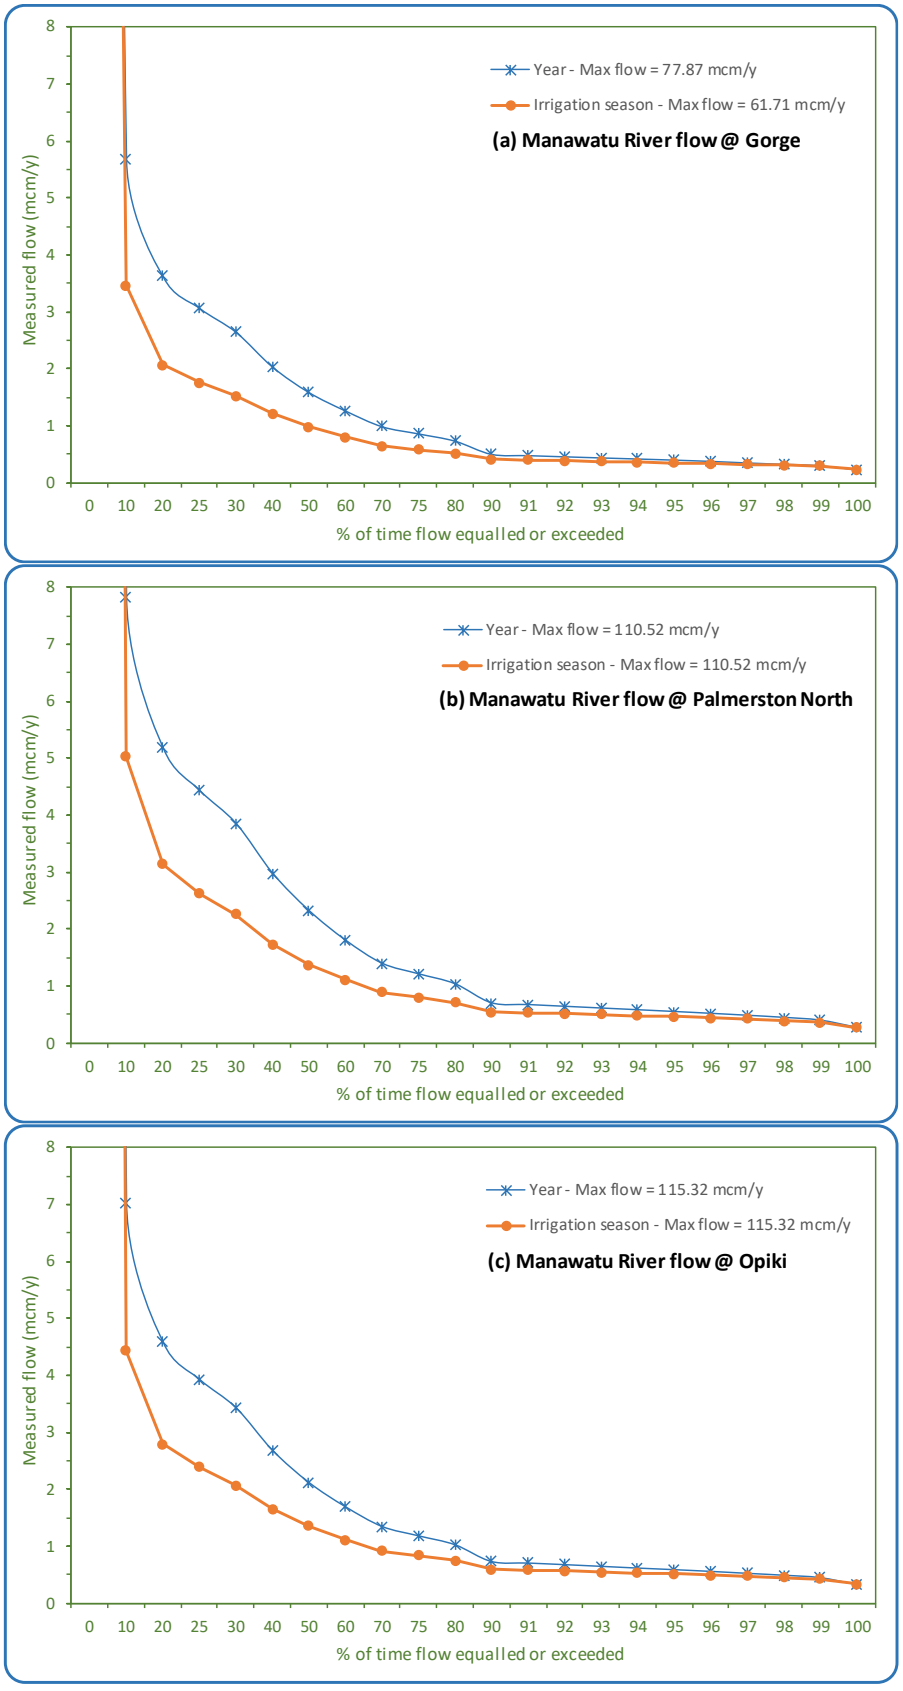

Figure 5-7. Flow duration curve (FDC) for the Manawatu River at three locations in the LMC showing percentage of time flows are equalled or exceeded (data from Henderson & Diettrich, 2007).

5.9.2 Mean annual low flow

Mean annual low flow (MALF) is the average of the lowest flow measured in each year of record. MALF values adopted in Table 5-1 from Henderson and Diettrich (2007) were calculated on water year (Section 4.6.4) to avoid the possibility of biasing the sample by summer time low flows, which can span two calendar years. Low flows can be taken as instantaneous flows or as moving means over a range of averaging intervals. Henderson and Diettrich (2007) low flow calculations use a one-day interval for reasons relating to surface water consents and abstractions.

5.10 Surface water-groundwater interaction

There are no concurrent surface water gauging data to enable identification of losses and gains from rivers and streams in the LMC. Regional-scale average groundwater level contour maps by Bekesi (2001) and Zarour (2008) suggest that most of the area's rivers and streams gain from groundwater. This is consistent with the conceptualisation by Russell (1989) of the area as a regional groundwater discharge zone. Figure 5-8 conceptually presents the main elements of the surface water network in the area using mean annual flows. From the figure, the following can be deduced:

1. Makino Stream is a gaining waterway.
2. Oroua River gains flow until it is joined by the Makino Stream near Almadale Slackline (Site R05), where it starts losing flow but at a relatively small rate
3. The Manawatu River gains flow from groundwater between the Manawatu Gorge and its confluence with the Kahuterawa Stream. Then it loses water in the area where it meanders in the general Opiki area. A small distance downstream from the flood gates, the river returns to gaining flow from groundwater.
4. Tokomaru River loses water along its length.

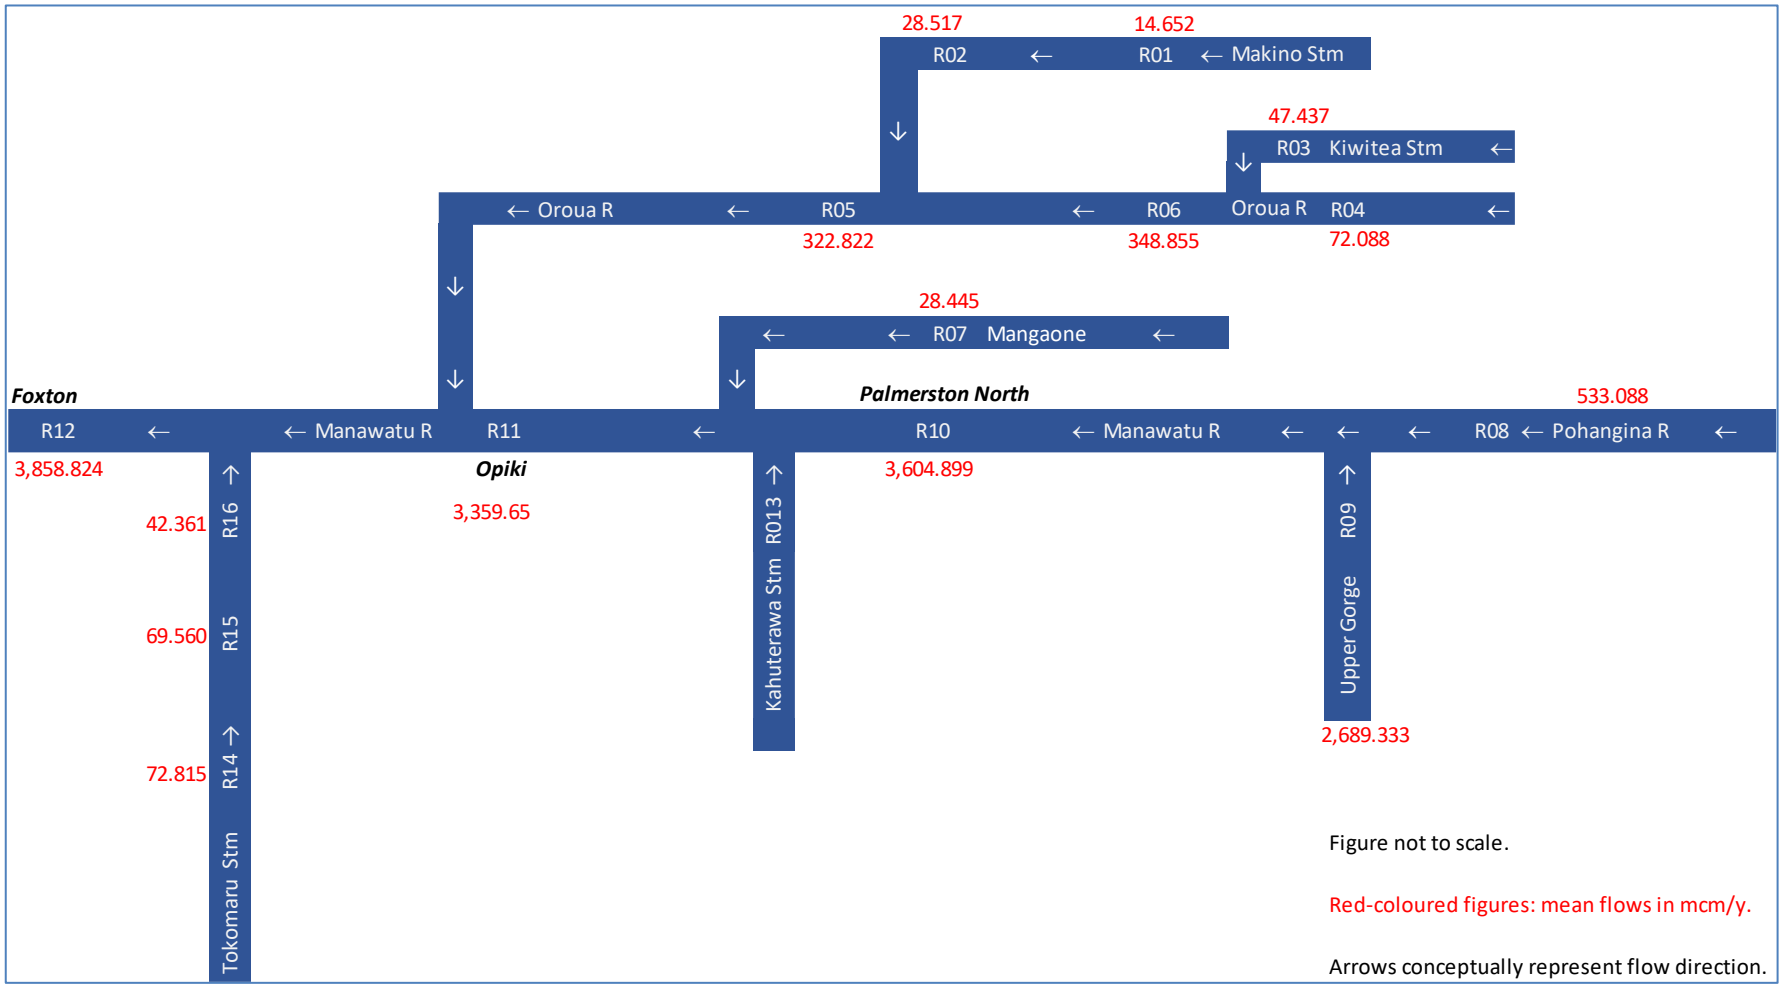

Figure 5-8. Conceptual presentation of main rivers and streams and their mean annual flows.

5.11 Surface water abstraction

Data to enable reliable and accurate assessment of surface water abstraction and use are lacking in the LMC. Water abstraction resource consents data were obtained from Horizons. This data set required tedious manual manipulation to structure it in a format that is usable to roughly estimate surface water takes. During the period 2010–2015, there were around 63 active surface water consents that allow the abstraction of up to 71 mcm of water per year (Table 5-2). In the absence of other data, it is assumed that all consented volumes are taken and that the period 2010–2015 represents long-term average conditions.

Table 5-2. Consented surface water takes active during the period 2010–2015.

Water use	Number of consents	Consented volume (m^3/y)
Drinking	6	17,613,440
Stock	11	1,260,820
Industrial	8	3,188,645
Irrigation	38	48,931,071
Total	**63**	**70,993,976**

5.12 Catchment water budget

The Manawatu River is the only surface water feature in the LMC that discharges directly to the Tasman Sea. The river drains the Upper Manawatu Catchment (c. 3,205 km^2) into the LMC (c. 2,678 km^2) through the Manawatu Gorge at a mean rate of about 2,670 mcm/y (Table 5-1 and Figure 5-8). Along its course from the Gorge to the Tasman Sea, the Manawatu River is joined to the southeast of Ashhurst by the Pohangina River which in average adds 533 mcm/y of flow to the Manawatu River. The Oroua River joins the Manawatu River to the south of Rangiotu, adding in average 323 mcm/y to the Manawatu River flow. The Manawatu, Pohangina and Oroua rivers are joined by a number of smaller surface waterways, the most important of which are Mangaone, Makino and Kiwitea streams.

In general terms, the LMC water budget can be expressed as follows:

$$\Delta S = P + G_{in} + Q_{in} - ET - G_{out} - Q_{out} - A_g - A_s \qquad 5\text{-}1$$

where ΔS is the change in storage, P is precipitation, G_{in} is groundwater inflow, Q_{in} is surface water inflow, ET is evapotranspiration, G_{out} is groundwater outflow, Q_{out} is surface water outflow, A_g is groundwater abstraction and A_s is surface water abstraction.

To solve Eq. 5-1 for long-term average conditions, we assume steady-state. Under steady-state conditions, storage does not change, i.e. $\Delta S = 0$. There is no groundwater inflow into the LMC, i.e. $G_{in} = 0$ and all other terms in Eq. 5-1 except groundwater discharge to the sea (G_{out}) can be reasonably estimated. Hence, we can use Eq. 5-1 to estimate G_{out} as shown in Table 5-3.

Table 5-3. LMC water balance parameters.

Parameter	value (m^3/y)	source
Precipitation ($\boldsymbol{P}$)	3,175,246,459	Table 4-7
Flow through the Manawatu Gorge ($\boldsymbol{Q_{in}}$)	2,700,064,140	Table 5-1
Evapotranspiration ($\boldsymbol{ET}$)	1,602,965,266	Table 4-7
River discharge to the Tasman Sea ($\boldsymbol{Q_{out}}$)	3,891,609,925	Table 5-1
Groundwater abstraction ($\boldsymbol{A_g}$)	53,019,173	Zarour (2008)
Surface water abstraction ($\boldsymbol{A_s}$)	70,993,976	Section 5.11
Groundwater discharge to the Tasman Sea ($\boldsymbol{G_{out}}$)	256,722,259	Calculated
Groundwater contribution to surface water flow	434,337,886	$RCH - A_g - G_{out}$

While Table 4-7 estimates groundwater recharge at about 744 mcm/y, Table 5-3 estimates total groundwater outputs at about 257 mcm/y. The difference between groundwater inputs (RCH) and outputs ($A_g + G_{out}$) represents the overall groundwater contribution to surface water flow (base flow) throughout the LMC area, estimated at about 434 mcm/y (Table 4-7). So, baseflow accounts for about 11% of the total surface water discharge to the Tasman Sea, which is the equivalent to about 58% of the total groundwater recharge in the LMC.

Chapter 6 Hydrogeology

6.1 Introduction

This chapter utilises information presented in the previous chapters and new data to draw a picture of groundwater in the LMC in terms of its occurrence and movement, the hydraulic characteristics of the host geological material, groundwater flow pattern, and groundwater interaction with other components of the hydrological cycle.

6.2 Hydrogeological classification of geological material

The ability of earth material to absorb and allow the movement of water has long been regarded as the most important aspect in hydrogeological studies. Accordingly, geological units are classically classified in terms that reflect their competence as water-bearing media. Literature defines an 'aquifer' as a saturated permeable geological unit that is capable of transmitting significant quantities of water under ordinary hydraulic gradients (e.g. Fetter, 2013; Freeze & Cherry, 1979). Contrastingly, an 'aquifuge' is an unsaturated impermeable geological unit which neither absorbs nor transmits water. An 'aquiclude' is a term used to describe a saturated geological unit that cannot transmit significant quantities of water under ordinary hydraulic gradients. The term 'aquitard' is used to describe the less-permeable zones in a stratigraphical sequence where strata may not be permeable enough to provide water to wells screened within them but still can transmit water in quantities that are significant in the long-term and/or at large-scale. Geological material that qualify to be described as aquifuge are normally considered hydrogeological basement or flow barrier (e.g. the bulk of the Torlesse greywacke basement rock throughout New Zealand). Most other geological strata are classified as either aquifers or aquitards and only very few units fit the strict definition of an aquiclude. As a result, there is a trend toward the use of the first two of these terms at the expense of the third (Freeze & Cherry, 1979). As the terms aquifer and aquitard are imprecise with respect to hydraulic conductivity,

these terms could be used in a relative sense. For example, silt strata in an interlayered sand-silt sequence may be considered aquitards, whereas we may consider them locally important aquifers in a silt-clay system. Table 6-1 presents typical ranges of hydraulic conductivity for the most common rocks and sediments in the world.

Table 6-1. Typical Hydraulic conductivity values for selected rocks and sediments (compiled from Bear, 1972; Heath, 1983; Younger, 2007).

$K\ (m/d)$	10^5	10^4	10^3	10^2	10	1	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}
Relative permeability	Pervious				Semi-pervious				Impervious				
Aquifer potential	Good					Poor				None			
Unconsolidated sand & gravel	Well sorted gravel		Well sorted sand or sand & gravel			Very fine sand, silt, loess, loam				Local loess			
Unconsolidated clay and organic					Peat		Layered clay			Fat/unweathered clay			
Consolidated rocks	Highly fractured rocks, karstic rocks and rocks with caves				Conglomerate, sandstone					Fresh limestone, dolomite		Greywacke, fresh granite	

6.3 Hydrolithostratigraphical setting

Building on the account of stratigraphy presented in Section 3.10, four main hydrolithostratigraphical units can be defined in the LMC:

1. Basement rocks: Permian-Early Cretaceous (mostly Triassic) indurated impervious rocks
2. Plio-Pleistocene marine rocks: poorly consolidated, predominantly marine sediments
3. Middle-Late Pleistocene unconsolidated terrestrial and marine deposits
4. Holocene alluvium and sands.

6.3.1 Greywacke basement rocks

This unit of commonly deformed, indurated sandstone with mudstone and other material interbeds lacks intrinsic and secondary permeability (aquifuge), except perhaps the weathered top few metres. Water in the weathered part of these rocks will evaporate and/or run into the nearest surface water drainage feature. These rocks constitute the hydrogeological basement for the LMC groundwater system and form its true left side boundary.

6.3.2 Plio-Pleistocene marine rocks

The Wanganui Basin in which the LMC lies is filled with up to more than 4 km of Plio-Pleistocene sediments. These strata dip to the southeast and are predominantly marine, but the Pleistocene Epoch part of the unit is characterised by alternating terrestrial and marine sequence corresponding to deposition during cold and warm periods, respectively.

The Plio-Pleistocene sequence in the LMC comprises interbeds of limestones, massive and sandy mudstones, carbonaceous and non-carbonaceous siltstones, pumiceous and non-pumiceous sandstones, and shallow water conglomerate with some lignite and shell beds. Castlecliffian stage strata of the Wanganui epoch represent the topmost part of this hydrogeological unit, which crops out in the upper part of the LMC where the unit is incised by the Oroua and Pohangina rivers, splitting them into three northeast-southwest aligned elongated chunks. These outcrop batches are longest near the ranges at the real left of the catchment, but they become shorter in the middle of the catchment and at its true right edge. In the lower part of the LMC, younger Quaternary deposits overlie the Plio-Pleistocene sequence. Overall, Plio-Pleistocene marine sediments are characterised by low to very low permeability that renders them as aquitard or aquiclude strata. However, they form an important regional recharge area for the LMC groundwater flow system (Figure 3-16 and Figure 4-18).

6.3.3 Middle-Late Pleistocene strata

Late Pleistocene (c. 340-12 ka BP) sediments in the LMC incorporate three main types of lithologies:

(1) alluvium: gravelly river alluvium deposited in cold periods, moderately sorted, extensive areal coverage, up to 10s of metres thickness, gentle dip, high to very high hydraulic conductivity
(2) beach sand: marginal marine sediment deposited in warm periods, extensive areal coverage, up to 10s of metres thickness, gentle dip, moderate hydraulic conductivity

(3) fan and landslide deposits: thin, poorly sorted, angular alluvial and colluvial deposits on steep slopes, limited areal coverage, low hydraulic conductivity, deposited in cold periods.

The terraced setting of the Middle-Late Pleistocene terrestrial and marine sediments in the LMC can affect groundwater flow in the area (Figure 6-1). In addition, many of these terraces are overlain by loess of variable thickness, potentially limiting their ability to receive recharge from rain.

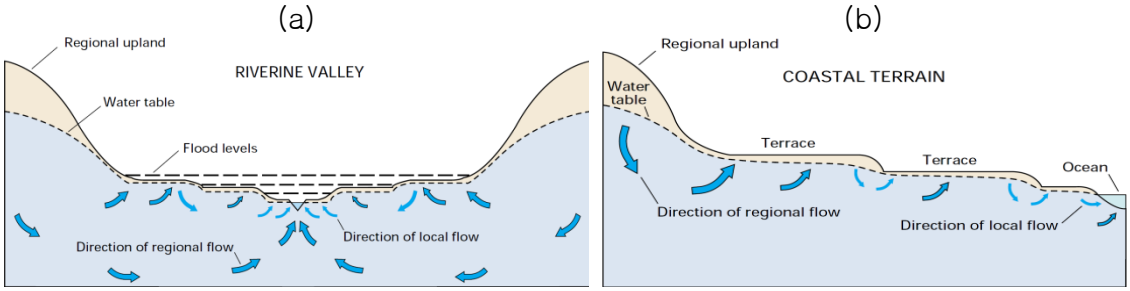

Figure 6-1. Effect of terraces on groundwater flow (after Winter *et al.*, 1998).

(a) In broad river valleys, small local groundwater flow systems associated with terraces overlie more regional groundwater flow systems. Recharge from flood waters superimposed on these groundwater flow systems further complicates the hydrology of river.

(b) In coastal terrain, small local groundwater flow cells associated with terraces overlie more regional groundwater flow systems. In the tidal zone, saline and brackish surface water mixes with fresh groundwater from local and regional flow systems.

6.3.4 Holocene alluvium and sands

Various types of Holocene age sediment occur in the LMC, including alluvium (Q1a), dune sands (Q1ds and Q1dm), alluvium fan (Q1f), and colluvium sediments (Q1l). The latter two lithologies are both limited in extent and thickness (Figure 3-2 and Table 3-1). Hence, they can be ignored in catchment-scale hydrogeological assessments.

The Holocene alluvium is characterised by high to very high permeability and occupy the lowest areas in the LMC. Hence, they are expected to exhibit unconfined aquifer conditions and a high level of groundwater-surface water

interaction. However, their limited thickness may constrain their usability as an aquifer.

Loose, windblown Holocene sands in active and inactive dunes in the lower part of the LMC enjoy moderate to high permeability (Table 6-1). Inter-dune swamps in this area would most probably represent the water table.

6.4 Aquifer properties

In hydrogeology, geological materials are characterised by their hydraulic conductivity (K) and specific yield (S_y). Aquifers however are characterised by transmissivity (T) and Storativity (S). Transmissivity is a measure of the amount of water that can be transmitted horizontally by a full saturated thickness of aquifer. It is calculated as the product of the hydraulic conductivity by the aquifer thickness ($T = Kb$) and conveniently expressed in m²/d units. Storativity is a measure of the volume of water that a permeable unit will absorb or expel from storage per unit surface area per unit change in hydraulic head (dimensionless, <1). In confined aquifers, storativity is termed storage coefficient and typically ranges between 5×10^{-5} and 5×10^{-3}. Storativity of unconfined aquifers is defined as the specific yield (S_y) and typically ranges between 0.01 and 0.3 (Kruseman & de Ridder, 1991).

There are several methods to evaluate aquifer properties including laboratory measurements, pumping and slug tests, geophysical methods and lithological analysis. Aquifer properties data sources in the LMC are limited to grain-size distribution and pumping test records.

6.4.1 Grain-size distribution analysis

Svensson (2014) studied methods for the estimation of hydraulic conductivity from grain-size analysis and compared them to laboratory and in-situ methods. She found little difference in results obtained from various hydraulic conductivity estimation methods from grain-size data when applied to well-sorted soils. However, the differences reach several orders of magnitude when dealing with poorly-sorted samples, i.e. soils with large uniformity coefficient (C_U). Uniformity

coefficient is calculated as D_{60}/D_{10}, where D_{60} is the particle size for which 60% of the material is finer and D_{10} is the particle size for which 10% of the material is finer, in consistent units. Material with C_U less than 3 is considered well sorted (uniform), C_U values between 3 to 5 indicate nonuniform material and C_U greater than 5 is indicative to highly nonuniform material.

Cooper (1999) reports on grain-size distribution analysis for 15 samples believed to be from the Last Interglacial marginal marine sand unit (Q5b) between Palmerston North to the Manawatu Gorge. Grain-size distribution plots in Cooper (1999) have been used to evaluate hydraulic conductivity using the Hazen and Gustafson methods (Table 6-2). According to Svensson (2014), the Hazen equation can be written as:

$$K = C_H \, D_{10}^2 \qquad 6\text{-}1$$

where K = hydraulic conductivity [m/s], C_H = empirical constant set to 0.01157 in Svensson (2014), and D_{10} = the particle size for which 10% of the material is finer [mm].

Svensson (2014) presents the Gustafson equation in the form:

$$K = E(C_U)\left(\frac{D_{10}}{1000}\right)^2 \qquad 6\text{-}2$$

Table 6-2. Hydraulic conductivity calculations based on grain-size distribution data reported in Cooper (1999).

Cooper (1999) description			Grain-size distribution data			Hazen	Gustafson				Hazen: Gustafson
Sample	Mean Size	Sorting	D_{10}	D_{60}	C_U	K (m/d)	$g(CU)$	E	$E(CU)$	K (m/d)	
1. Dairy 1	Fine sand	Extremely poorly sorted	0.100	0.180	1.80	9.9965	3.96	0.23	6,760.99	5.8415	1.71
2. Dairy 3	Fine sand	Very poorly sorted	0.100	0.200	2.00	9.9965	3.72	0.24	8,579.71	7.4129	1.35
3. Dairy 5	Coarse silt	Extremely poorly sorted	0.001	0.060	60.00	0.0010	1.66	0.10	3,127.34	0.0003	3.70
4. ANZAC 1	Coarse silt	Extremely poorly sorted	?	0.025	?	?	?	?	?	?	?
5. ANZAC 4	Fine sand	Extremely poorly sorted	0.080	0.150	1.88	6.3977	3.86	0.24	7,511.22	4.1534	1.54
6. ANZAC 8	Fine sand	Very poorly sorted	0.020	0.230	11.50	0.3999	1.98	0.16	8,548.40	0.2954	1.35
7. ANZAC 9	Fine sand	Very poorly sorted	0.030	0.230	7.67	0.8997	2.17	0.18	10,539.28	0.8195	1.10
8. ANZAC 11	Medium sand	Moderately sorted	0.300	0.650	2.17	89.9683	3.56	0.25	9,708.65	75.4945	1.19
9. Burgess 1	Fine sand	Extremely poorly sorted	0.030	0.160	5.33	0.8997	2.41	0.20	12,115.65	0.9421	0.95
10. Burgess 3	Fine sand	Very poorly sorted	0.080	0.160	2.00	6.3977	3.72	0.24	8,579.71	4.7442	1.35
11. Forest Hill 1	Medium sand	Extremely poorly sorted	0.001	0.850	850.00	0.0010	1.71	0.06	686.51	0.0001	16.85
12. Forest Hill 4	Fine sand	Extremely poorly sorted	0.010	0.100	10.00	0.1000	2.04	0.16	9,228.19	0.0797	1.25
13. Tuapaka 4	Fine sand	Extremely poorly sorted	0.050	0.180	3.60	2.4991	2.79	0.23	12,785.03	2.7616	0.90
14. Tuapaka 10	Fine sand	Very poorly sorted	0.001	0.160	160.00	0.0010	1.63	0.08	1,745.10	0.0002	6.63
15. Tuapaka 3	Medium sand	Extremely poorly sorted	0.010	0.180	18.00	0.1000	1.84	0.14	6,568.98	0.0568	1.76

According to Svensson (2014), the function $E(C_U)$ is expressed through the following connections:

$$E(C_U) = 10.2x10^6 \left(\frac{E^3}{1+E}\right)\left(\frac{1}{g(C_U)^2}\right) \quad 6\text{-}3$$

$$E = 0.8\left(\frac{1}{2\ ln(C_U)}\right) - \left(\frac{1}{{C_U}^2 - 1}\right) \quad 6\text{-}4$$

$$g(C_U) = \left(\frac{1.3}{log_{10}\ C_U}\right)\left(\frac{{C_U}^2 - 1}{{C_U}^{1.8}}\right) \quad 6\text{-}5$$

Hydraulic conductivity estimates from grain-size distribution data using the Hazen and Gustafson equations presented in Table 6-2 fall within the expected range for sand and poorly sorted sand with gravel as depicted in Table 6-1. However, the results presented in Table 6-2 show that the difference between the Hazen and Gustafson equations hydraulic conductivity estimates are proportionally related to uniformity coefficients. Since poor sorting reduces effective porosity and permeability, Gustafson equation results may provide more realistic results for the tested samples.

6.4.2 Pumping tests

Pumping test data are useful for aquifer typifying and evaluation of aquifer parameters, particularly transmissivity (T) and storativity (S). There are records of quite a few pumping tests in the LMC. The tests are a mix of constant discharge rate and step-drawdown types, and some have recovery data.

It has been chosen not to use aquifer test data in this research for the following reasons:

1. Pumping test data are not readily available from Horizons Regional Council.
2. Most pumping test records at Horizons are saved in digital format that require dated proprietary software that is not available to the author of this thesis.

3. From the author's experience, having worked at Horizons Regional Council from 2004 to 2011, most pumping tests undertaken in the LMC severely breach pumping test analysis methods assumptions, making them unreliable as a source of aquifer parameter data.
4. Many tests are short to a level that does not allow reliable aquifer typifying and, consequently, the selection of a suitable analysis method.
5. Most available records are for single-well pumping tests, which cannot be used to estimate storativity.
6. As a rule, the aquifer thickness is unknown and, in most cases, well construction data are not available, which does not enable calculation of hydraulic conductivity values from transmissivity estimates.
7. Many pumping tests failed to use reliable methods to measure discharge rates during the tests, which introduces a major source of uncertainty in the tests and their results.
8. Most of the constant rate tests failed to maintain constant discharge rate throughout their durations.
9. Available specific capacity (Q/s) data are largely consistent with pumping test data, but neither can be used to calculate hydraulic conductivity with confidence.

Despite the above, the following can be deduced from pumping tests in the LMC based on the author's experience in the area having audited few reasonably good quality pumping tests and from limited published work:

1. Time-drawdown curves suggest unconfined aquifer conditions, including many relatively deep wells, e.g. the 40 m deep Well 336093 (Figure 6-2).
2. Step-drawdown tests indicate low efficiency for many wells, possibly due to lack of gravel pack and unmethodological well screen design. It is normal in the LMC to see declining well efficiencies due to siltation. For example, the efficiency of a public water supply well in Foxton Beach dropped to a level that necessitated its replacement.

3. Hydraulic conductivity for most screened material in the LMC falls in the clean sand–clean gravel range (≥1 m/d) (Figure 6–3).
4. Although there are no pumping test data to support this assumption, hydraulic conductivity for non–gravelly material in the LMC are expected to be within the sand–silt range, i.e. 1–0.0001 m/d, as suggested in Table 6–1, and Table 6–2.

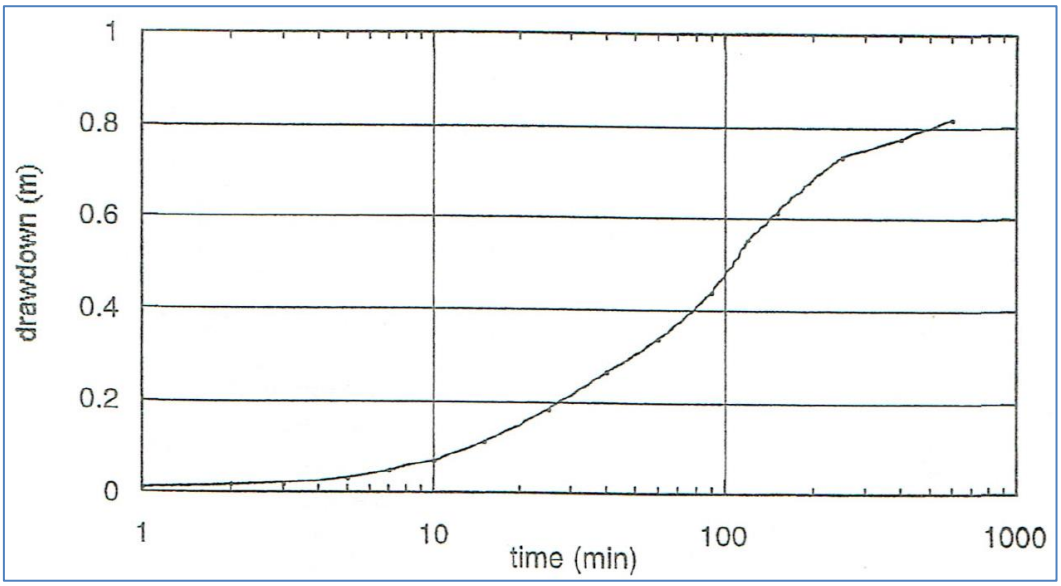

Figure 6–2. Constant rate pumping test time–drawdown semi–log plot for Well 336093 (40 m deep) in Aokautere, east of Palmerston North. The S–shaped time–drawdown curve is typical of unconfined aquifer with delayed yield (figure sourced from Schumacher, 1999).

6.5 Groundwater piezometry

Hydraulic or piezometric head is a measurement of liquid pressure above a geodetic datum (Chanson, 2004; Mulley, 2004). For groundwater, it is also termed groundwater level and is useful for determining the aquifer 'fullness' and flow direction. Groundwater level data are essential for calibrating groundwater models.

Groundwater level data in the LMC are collected by Horizons Regional Council and available in digital format from their groundwater database. Table C–1 in Appendix C summarises groundwater level data availability in the LMC.

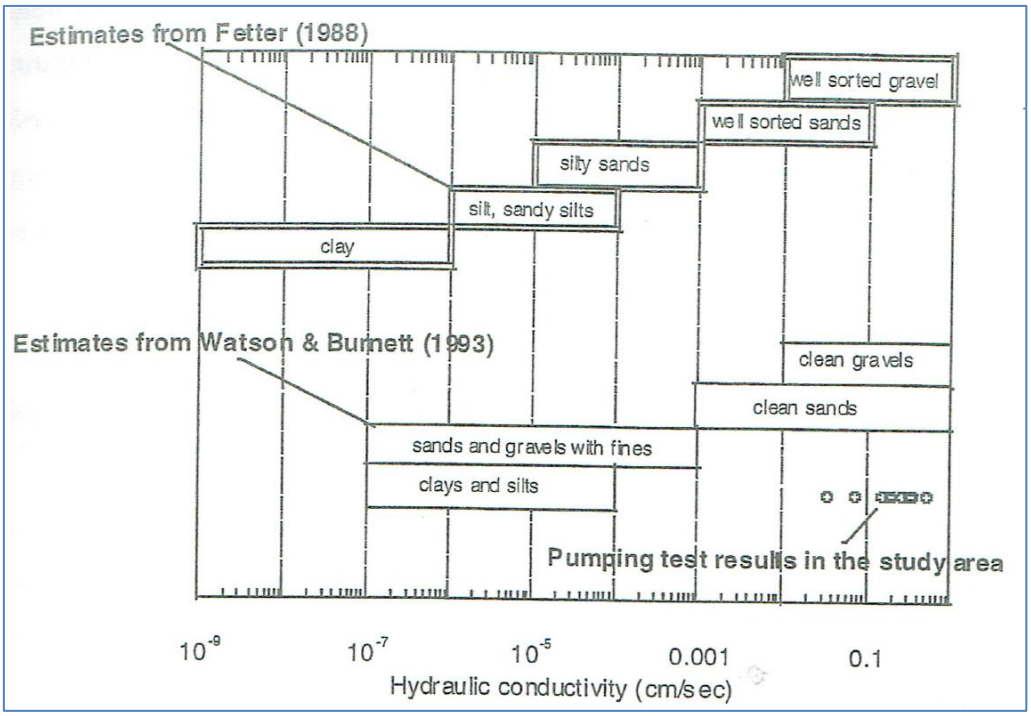

Figure 6-3. Comparison of hydraulic conductivity values obtained from pumping tests in the LMC to literature values (figure sourced from Schumacher, 1999). Screen length is used in the calculations as a proxy to aquifer thickness.

6.5.1 Groundwater level variability in time

Figures C-1 through C-84 in Appendix C present groundwater level hydrographs for monitoring wells in the LMC. They also show long-term mean, yearly mean, cumulative mean, deviation from the mean (mean deviation), and cumulative deviation from the mean (CDFM). The figures include information on the land elevation at the well site, screen extent, mean groundwater level and groundwater level standard deviation (STDEV).

The groundwater level hydrographs have been visually inspected for trend and classified into three categories: (1) declining, (2) steady, and (3) rising. Rising groundwater levels are indicated by CDFM curves concaving underneath the mean deviation curve, and rising cumulative mean curves (e.g. Figure 6-4). The opposite curve configuration implies dropping groundwater levels. The shape of the yearly mean curve also helps in the interpretation. The map presented in Figure 6-5 depicts groundwater trends in the LMC.

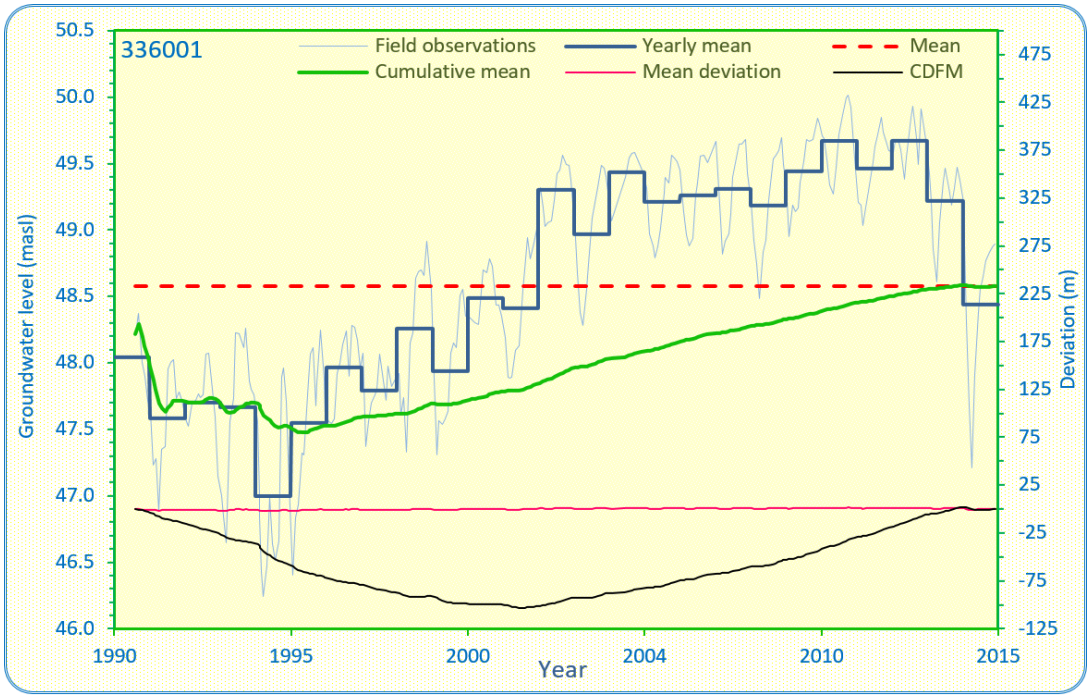

Figure 6-4. Example of groundwater level hydrograph plots presented in Appendix C.

Groundwater level records for four wells have been excluded because they were found to be old and/or too short to be relevant and/or useful in the groundwater level trend analysis presented here (wells 325009, 333035, 336017 and 354003 presented in Figures D-6, D-24, D-40 and D-82, respectively).

Visual inspection of groundwater level hydrographs is subjective, but useful when the data is plotted in a variety of forms and supported by basic statistics like standard deviation. Examination of such groundwater level hydrographs in the LMC reveals that the effects of the highest recorded rainfall in the area in 2004 has been very short-lived. However, the low rainfall in 2014 has noticeably affected groundwater levels in the catchment.

Overall, inspection of groundwater data reveals no extreme trends and the magnitude of groundwater level fluctuations seems to be generally small, mostly less than 1 m and very seldom above 2 m from the long-term average.

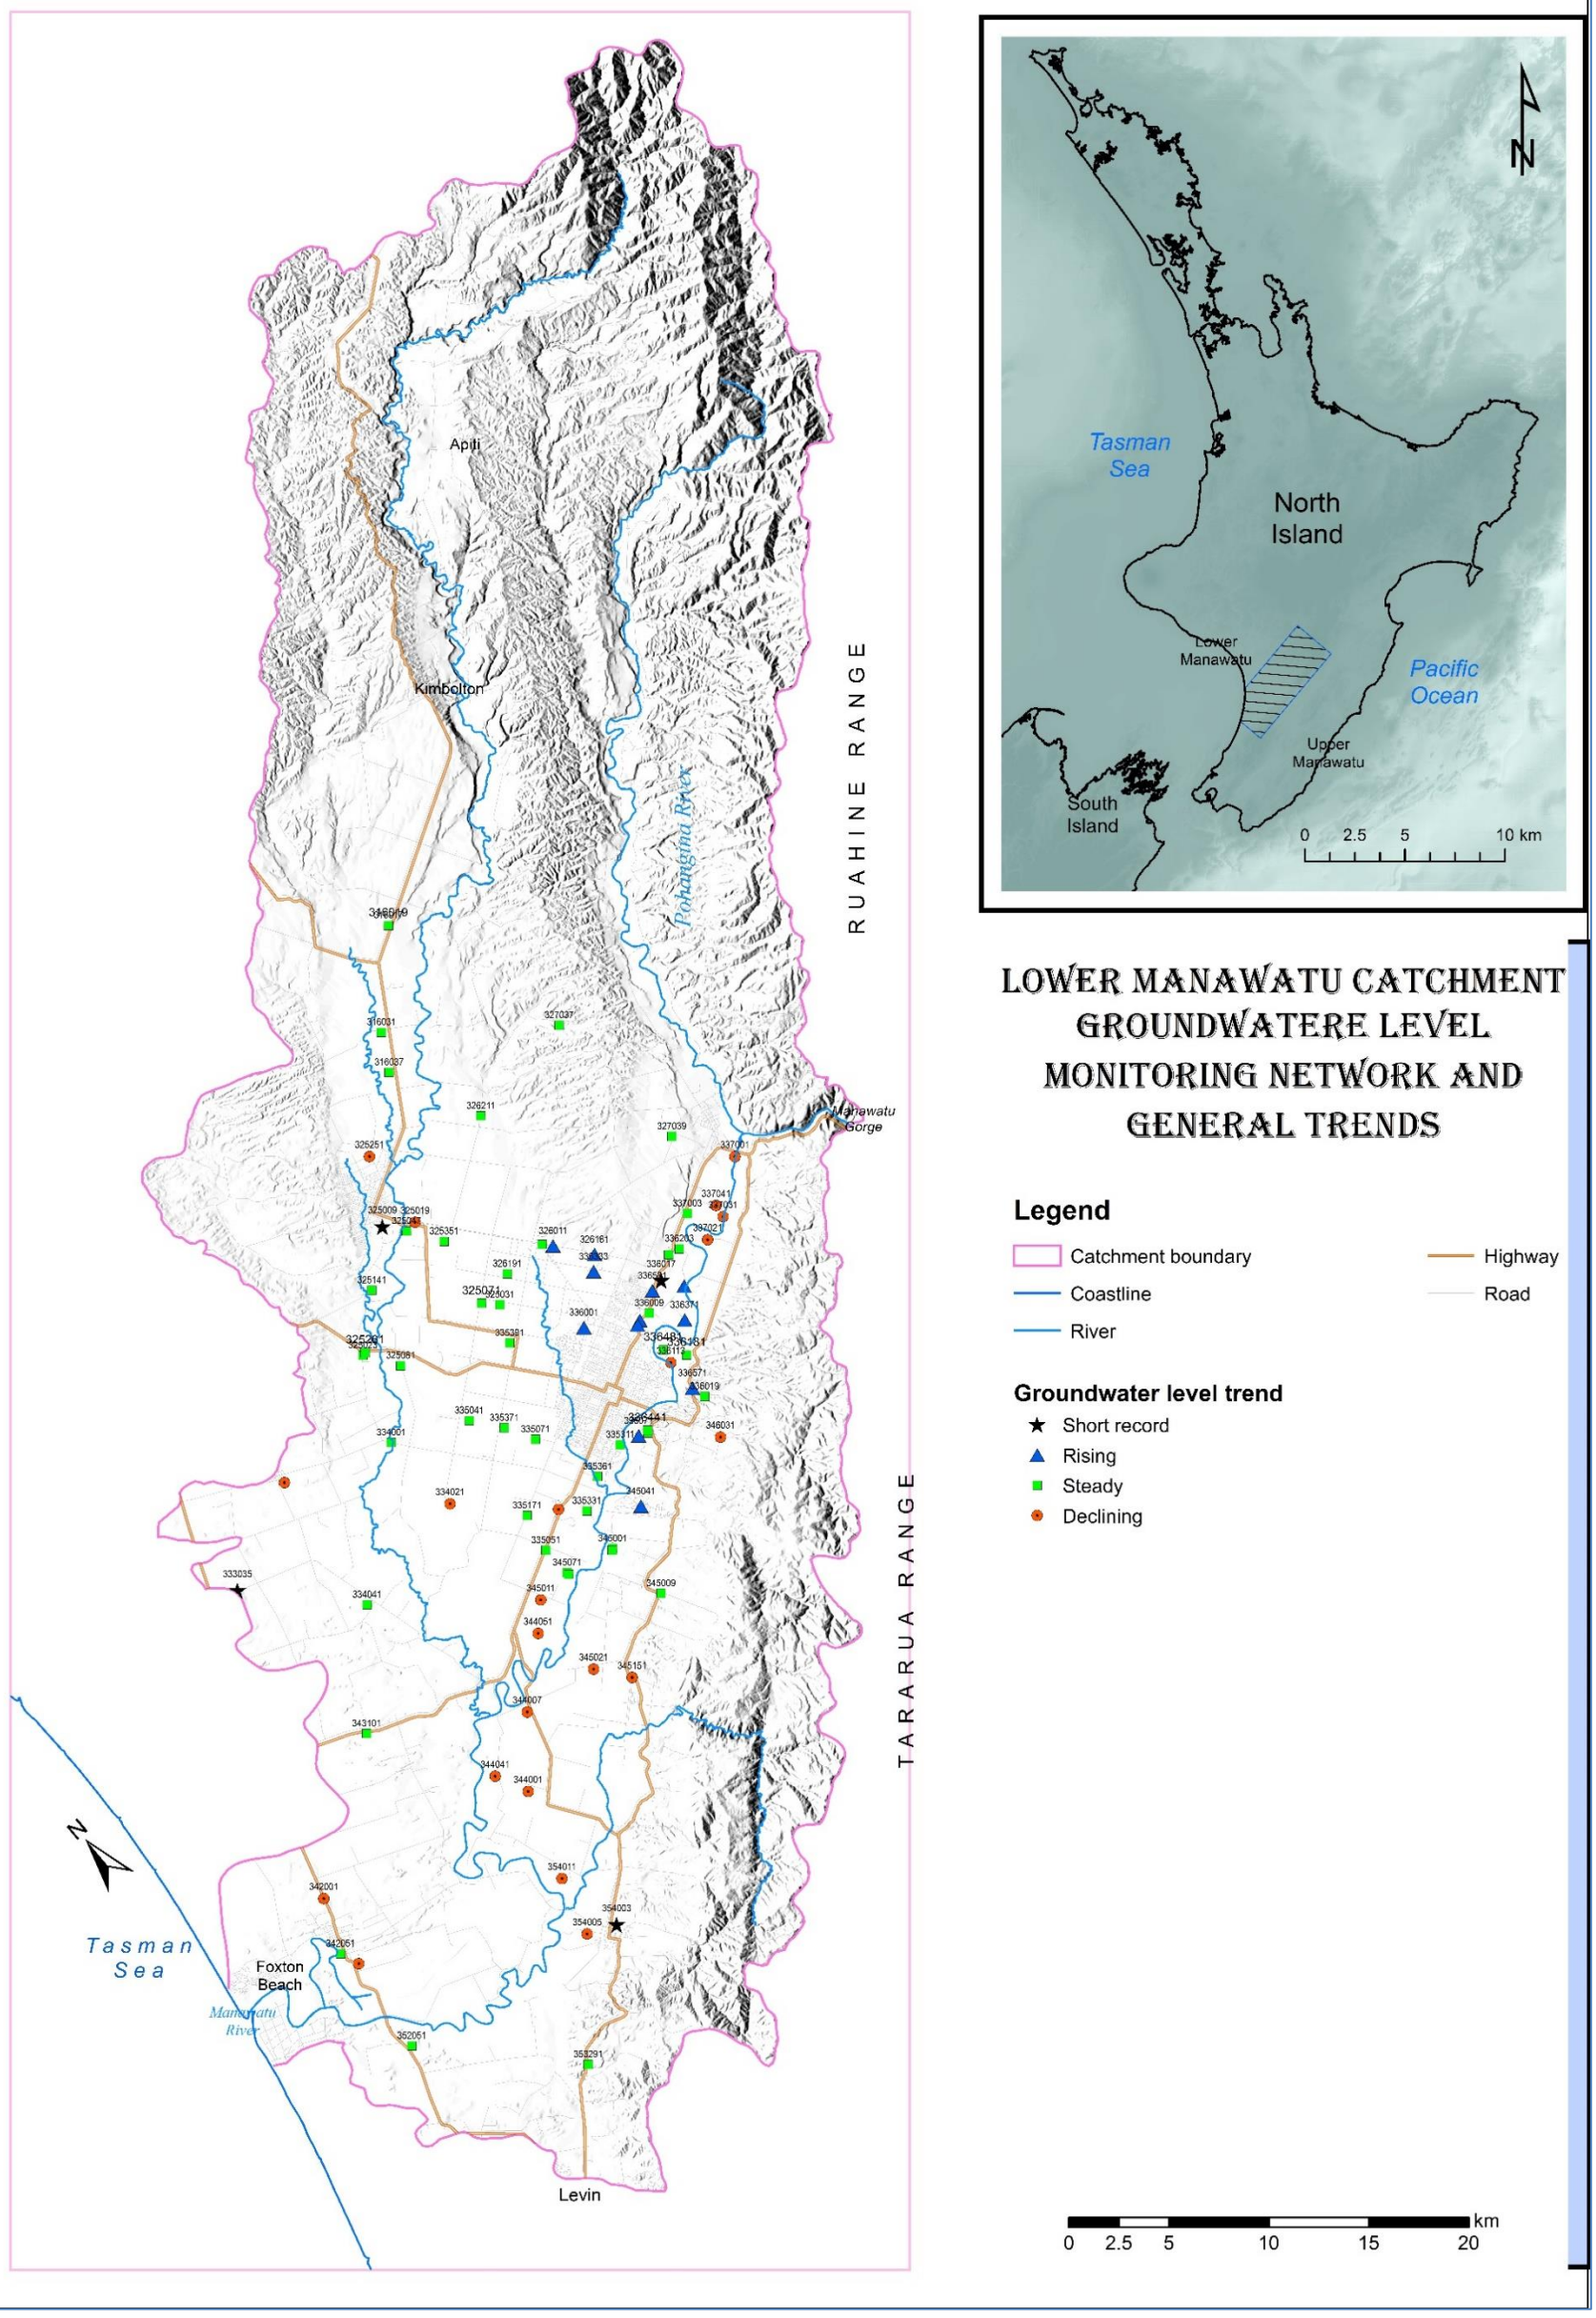

Figure 6-5. Groundwater level trends in the LMC.

There seems to be no correlation between well depths and groundwater level trends. However, a spatial pattern in groundwater level trends can be seen in the map presented in Figure 6-5. Groundwater levels seem to have been persistently rising at the eastern and southern outskirts of Palmerston North. This may be due to irrigation returns from prolonged market garden irrigation in the area.

Slightly, but persistently declining groundwater levels can be noticed in the low-lying area between Opiki, Shannon, Tokemaru and Tiakitahuna. Elsewhere, groundwater levels have been steady with only few outliers.

Most examined groundwater level hydrographs exhibit a seasonal pattern. In general, groundwater levels are highest just before the start of the irrigation season and lowest around its end.

6.5.2 Groundwater level change with depth

Schumacher (1999) constructed hydrogeological cross-sections and fence diagrams to depict the change in head with depth in the LMC. His diagrams denote decreasing head with depth in recharge zone settings locations such as the Pohangina Anticline, and upward hydraulic head gradients in groundwater discharge zone setting areas such along the Manawatu River near Palmerston North. Zarour (2008) showed that the 1:5 upward hydraulic gradient exhibited by the Whakarongo multi-level piezometer setup is gradual (Figure 6-7), indicating groundwater discharge settings in a continued aquifer system rather than a sequence of aquifers and aquitards.

6.5.3 Piezometry and groundwater flow

Groundwater flows from higher to lower head positions. Groundwater head is a measure of energy per unit weight of water and is measured in units of length relative to datum, e.g. masl. Groundwater head is a combined expression of kinetic, gravitational and fluid pressure energies. Kinetic energy can be ignored in groundwater due to its normally slow flow velocities.

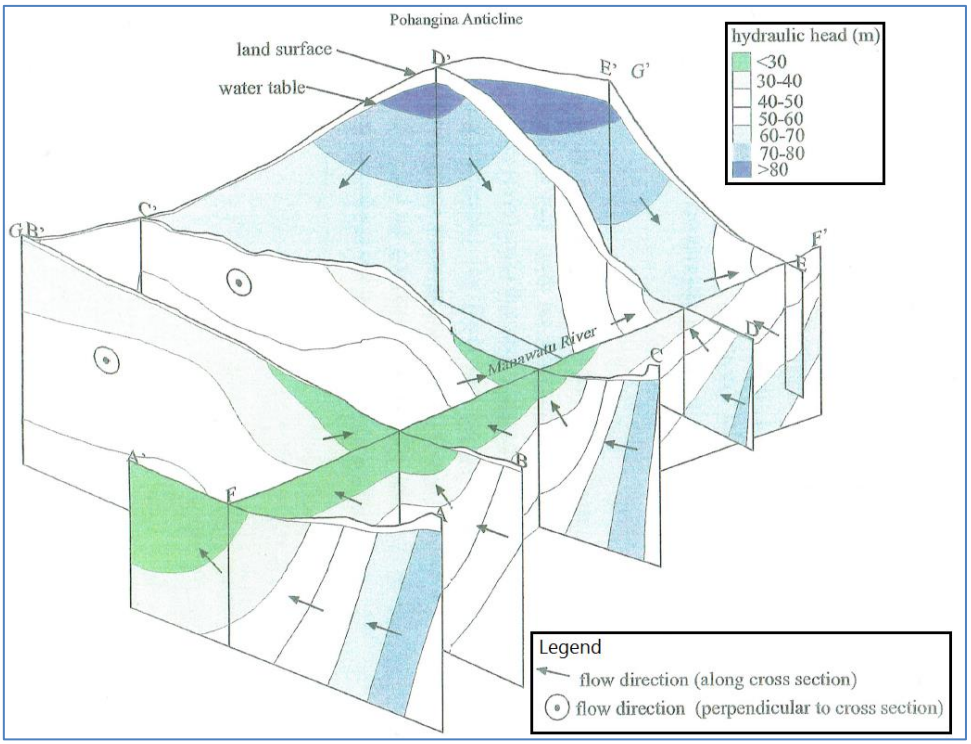

Figure 6-6. Hydrogeological fence diagram (after Schumacher, 1999).

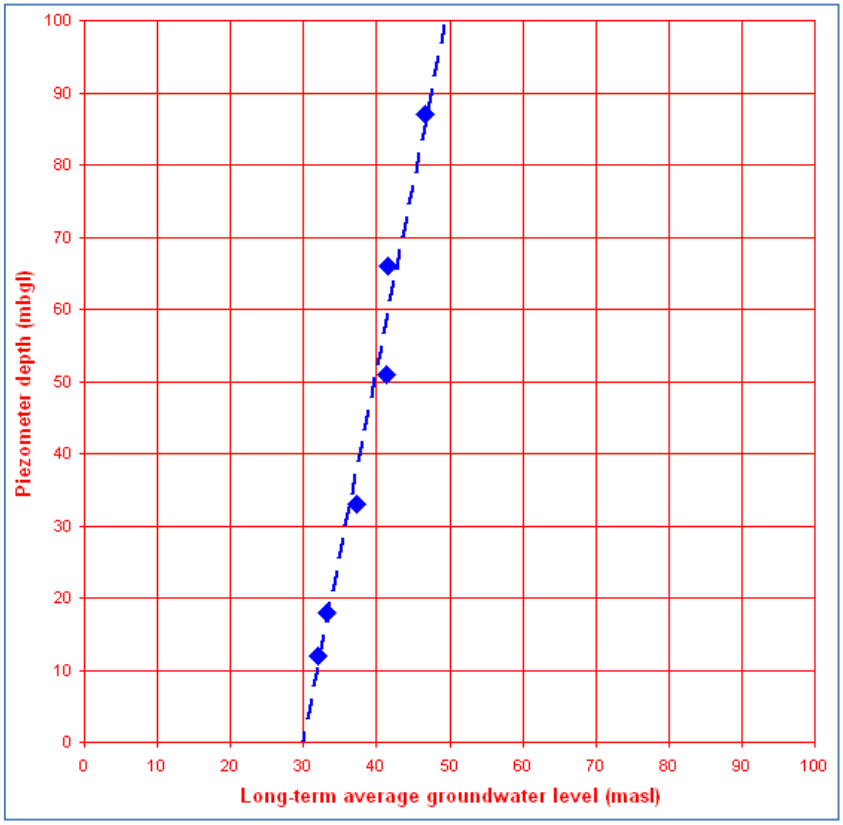

Figure 6-7. Relation between screen depth and head as observed in the Whakarongo multi-level piezometer setup (after Zarour, 2008).

Contour maps are commonly used to represent the spatial distribution in groundwater head. Known as piezometric maps, they provide a means to assess flow directions, which are perpendicular to groundwater level contour lines. Since there is no evidence of disconnect between surface water and groundwater in the LMC, surface water elevations can be incorporated in piezometric maps.

Figure 6-8 presents a piezometric map for the LMC drawn using long-term average groundwater level and surface water height (stage) monitoring. The piezometric map indicates that groundwater flow is generally from northeast to southwest, aligned to the dip of the geological strata.

The relatively dense contours in the upper part of the LMC indicate low transmissivity whereas the flatter hydraulic gradients between Palmerston North and the ocean indicate relatively high transmissivity.

The piezometric map presented in Figure 6-8 provides a basic picture of average surface water-groundwater interaction conditions in the LMC. Bending piezometric contour lines with tips pointing upstream indicate groundwater discharge zone settings (Figure 5-3a). An example on such settings is found in the Pohangina Valley. Conversely, the V-shaped piezometric contours along most of the Oroua River upstream of Feilding indicate losing river condition, where surface water recharges the underlying aquifer. Below Feilding and Palmerston North, the Oroua and Manawatu rivers predominantly gain flow from groundwater. The Mangaone Stream seems to be largely dependent on groundwater, acting as a drain along nearly its entire length.

Understanding groundwater-surface water interaction and flow directions is important for efficient allocation of both resources. It is essential to determining surface water and groundwater environments that could be affected by various land use and waste disposal activities. Numerical modelling could be a useful tool for improving this understanding.

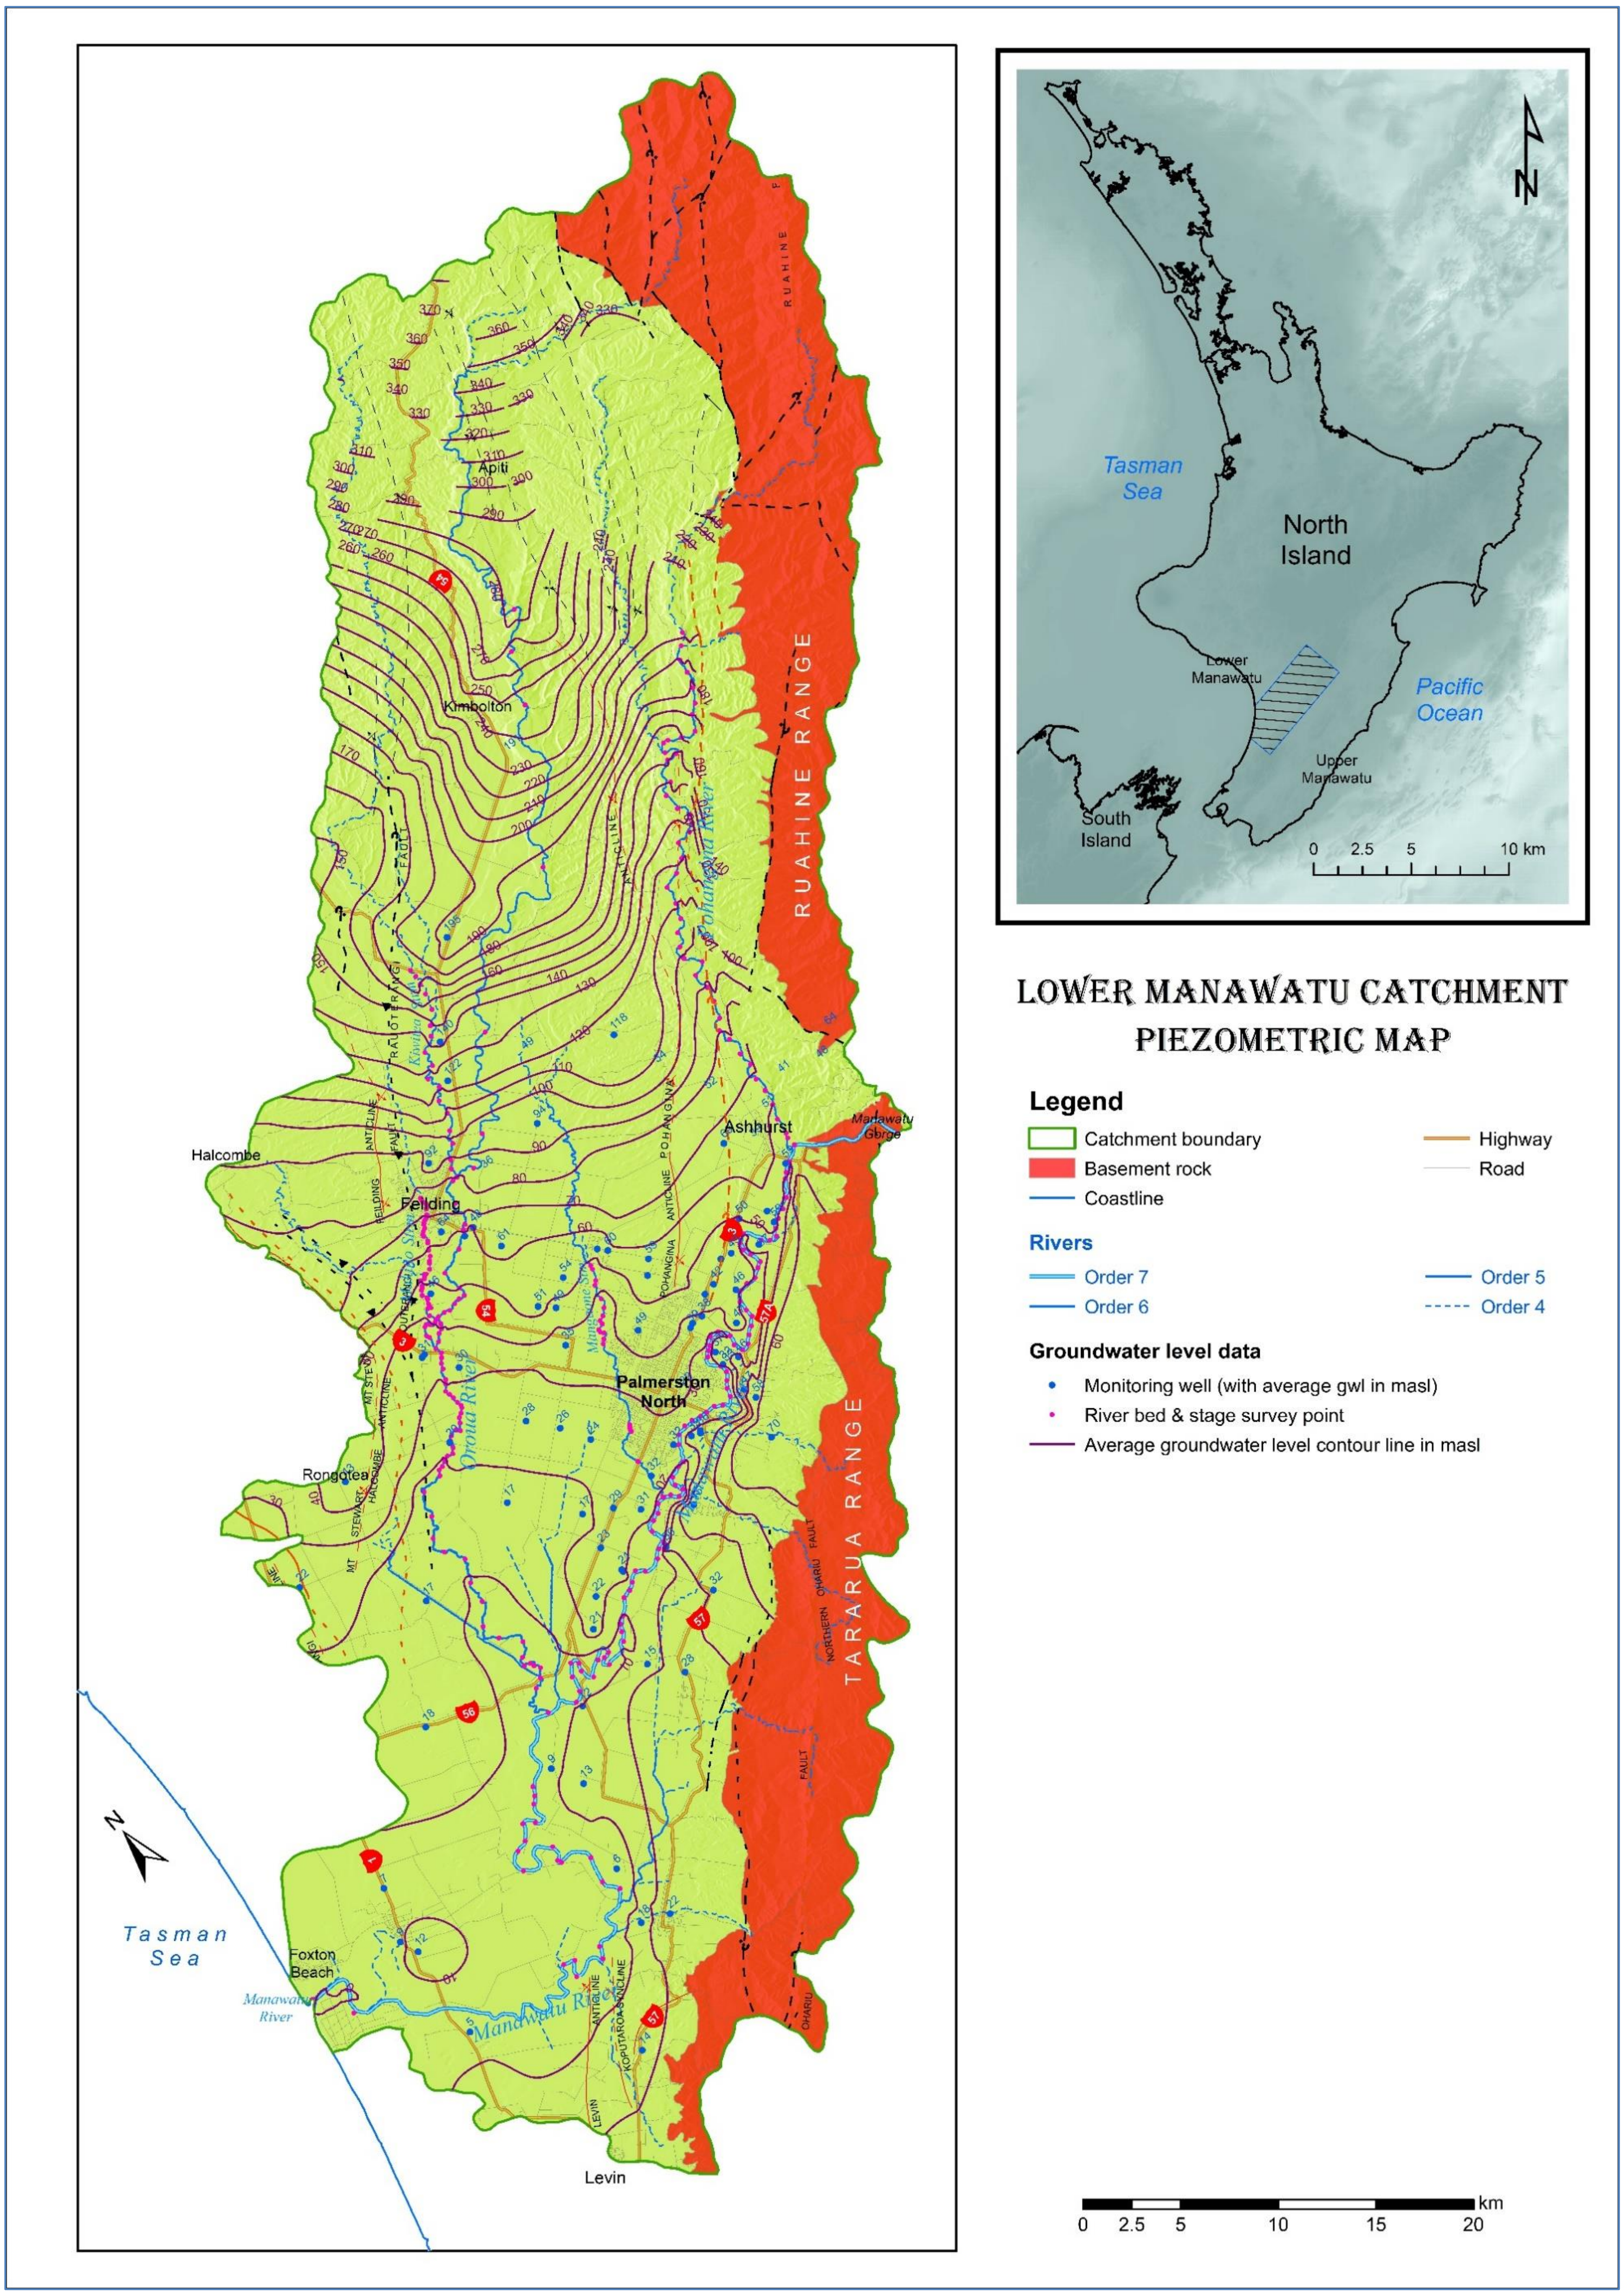

Figure 6-8. Piezometric map for the LMC drawn using long-term average groundwater level and surface water stage monitoring data.

The effect of the Pohangina Anticline on piezometry is prominent in the outcrop area of the Last Interglacial beach deposits in the middle of the catchment, to the northeast of Palmerston North (near Stoney Creek Lane). The topographical high on the marine terraces apparently coincides with a groundwater divide, separating flow towards the Manawatu River from flow towards the Mangaone Stream, then separating flow towards the Manawatu River from flow towards the Oroua River.

The area's topographical, geological and hydrological settings favour the development of topography-controlled groundwater flow system like the system presented in Figure 6-9. The groundwater flow system in the LMC is most probably multi-scaled like the system shown in Figure 6-10.

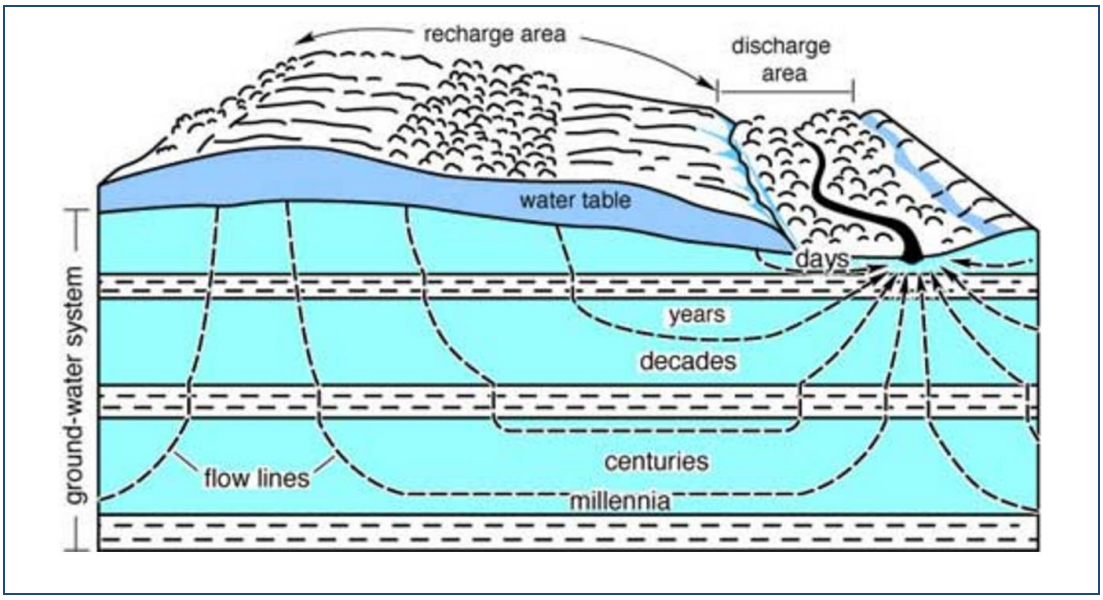

Figure 6-9. Schematic diagram for a topographically controlled groundwater system and flow times (after Buchanan & Buddemeier, 2005).

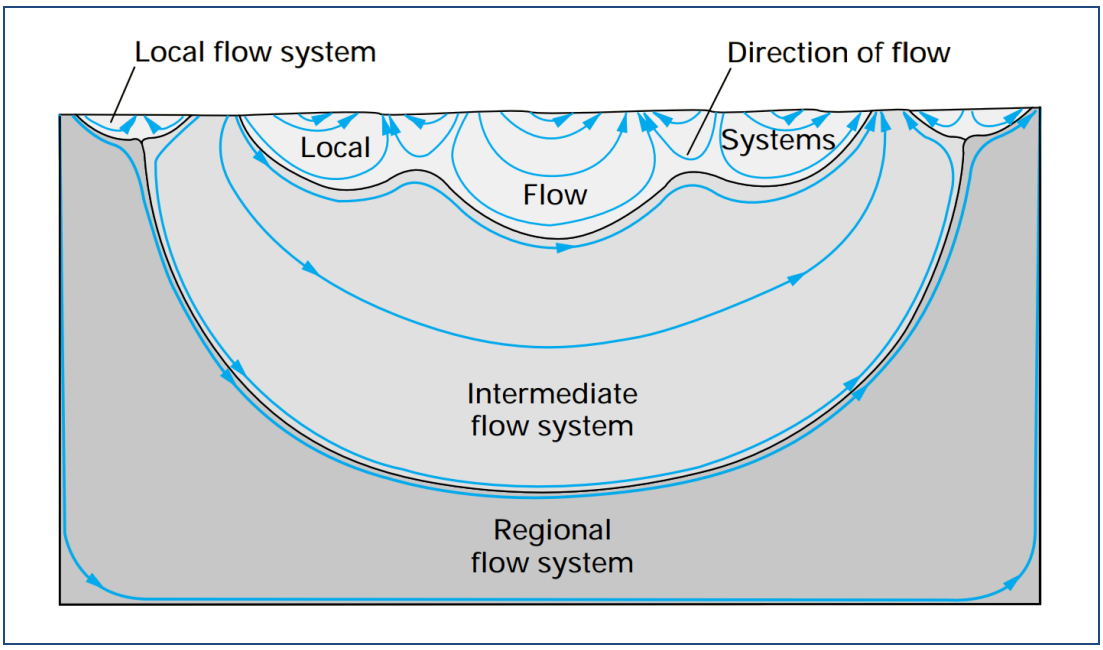

Figure 6-10. Schematic diagram showing multi-scale flow system (after Winter *et al.*, 1998).

Chapter 7 Hydrochemistry

7.1 Introduction

The aptness of water for various purposes is determined by its quality. Hence, early hydrogeochemical studies were mainly aimed at determining groundwater fitness for municipal and agricultural purposes (Domenico & Schwartz, 1990). In the 1940s, researchers started developing hydrogeochemical techniques to decipher the processes that control groundwater quality evolution along flow paths with the aim to complement and enhance hydrogeological investigation methods. Groundwater quality is also studied to gauge the effect of land and water resource management practices and interventions on the environment.

7.2 Processes controlling groundwater quality

Water is branded as the universal solvent because it can dissolve more substances than any other material (Brezonik & Arnold, 2011). Most inorganic substances are electrolytes, dissolving in water to form ions. Organic substances can also dissolve in water but they are usually nonelectrolytes and, therefore, they mostly dissolve in water as nonionic molecules (Domenico & Schwartz, 1990).

During its flow through geological materials under the ground, groundwater interacts with minerals and it is affected by the subsurface environment in a manner that changes its composition. Groundwater quality can change due to one or any combination of the following processes (e.g. Appelo & Postma, 2005; Fetter, 2013; Freeze & Cherry, 1979; Hem, 1985; Lloyd & Heathcote, 1985; Winter *et al.*, 1998):

1. **Mixing, dilution and concentration** can change groundwater composition. For example, evapotranspiration condenses chemicals in precipitation and recharge waters. The extent of condensation can be estimated by studying the change in concentration of conservative ions such as chloride (Cl^-).

Groundwater can also mix with surface water or seawater, and it can become polluted due to mixing with leachate from various anthropogenic activities.

2. Acid-base reactions involve the transfer of hydrogen ions (H^+) among solutes dissolved in water, which affects the effective concentrations of dissolved chemicals. pH is a notation for H^+ concentration (activity) that equals the negative logarithmic-scale of the H^+ concentration. It ranges from 0 to 14, with the middle point (pH 7) being neutral (neither acidic nor basic). Lower pH values represent larger H^+ concentrations (acidic solutions), and higher pH values represent smaller H^+ concentrations (basic or alkaline solutions). Many metals stay dissolved when pH values are low, but they precipitate from solution when pH increases.

3. Mineral dissolution-precipitation reactions: Mineral solubility and kinetics determine the release of cations into groundwater. Dissolution of carbonate and silicate minerals is largely driven by the action of carbon dioxide (CO_2), which dissolves in rainwater in the atmosphere to produce diluted carbonic acid (H_2CO_3) (Eq. 7-1). CO_2 is also produced within the soil zone by biochemical processes like the decay of organic matter (e.g. Eq. 7-2). H_2CO_3 affects the solubility of minerals as it increases its acidity (lowers water pH) in the process of creating bicarbonate ions (HCO_3^-) (Eq. 7-3) and then, if conditions permit carbonate ions (CO_3^{2-}) (Eq. 7-4).

$$CO_2 + H_2O \rightleftarrows H_2CO_3 \quad 7\text{-}1$$

$$CH_2O + O_2 \rightarrow H_2O + CO_2 \quad 7\text{-}2$$

$$H_2CO_3 \rightleftarrows HCO_3^- + H^+ \quad 7\text{-}3$$

$$HCO_3^- \rightleftarrows CO_3^{2-} + H^+ \quad 7\text{-}4$$

Dissolution of carbonate-bearing rocks aided by H_2CO_3 is responsible for the existence of calcium (Ca^{2+}) and magnesium (Mg^{2+}) in groundwater. Weathering of silicate rock minerals (e.g. feldspar and biotite) releases solutes into groundwater and forms clays. Weathering of cation-rich clays

forms cation-poor clays. All these reactions consume CO_2 and, consequently, change groundwater's pH. During recharge, the percolating water remains in contact with the atmosphere and soil CO_2 (open system) up to a certain depth. However, below that level, diffusive groundwater interaction with the soil and atmosphere become negligible and groundwater quality evolution proceeds with a fixed quantity of atmospheric CO_2 (closed system). Therefore, the prevalence of open or closed system conditions with respect to CO_2 is important during the early evolution of groundwater chemical composition.

According to Palmer and Cherry (1984), a groundwater system may be described as being 'open' with respect to CO_2 if its pores contain sufficient mass of CO_2 such that the soil gas partial pressure (pCO_2) in this space does not significantly change as the pore water equilibrates with it, or if the rate of CO_2 production in the soil is comparable to the rate at which it is lost to the aqueous phase within the pore space. Below the capillary fringe, the pores are filled with water and there is little or no replenishment of gaseous CO_2 to the water from the atmosphere, in which case the system is considered as being 'closed' with respect to CO_2. Initial mineral dissolution may occur under either open or closed conditions with respect to CO_2, depending on the soil conditions and the availability of the mineral phase.

Dissolution of minerals can take place as long as the groundwater is under saturated with respect to these minerals. Precipitation of minerals take place when their concentrations exceed their saturation indices (SI) resulting in minerals forming from ions dissolved in water. For example, iron hydroxide ($Fe(OH)_3$) will form when iron dissolved in groundwater encounters oxygen (O_2) dissolved in surface water, which is common in areas of groundwater seeps and springs. However, precipitation of minerals is not a prompt process and, therefore, groundwater may become supersaturated with respect to certain minerals.

4. Sorption and ion exchange: Sorption (or adsorption) is a process in which solutes (ions or molecules dissolved in liquid) become attached to the surfaces (or near-surface parts) of solid materials, either temporarily or permanently. Thus, solutes in groundwater can be sorbed (adsorbed) either to the aquifer material or to particles suspended in the groundwater. Release of sorbed chemicals to water is termed desorption. When ions attached to the surface of a solid are replaced by ions that were in water, the process is known as ion exchange. For example, Ca^{2+} and Mg^{2+} ions in groundwater can be exchanged for sodium ions (Na^{+}) on the surface of the aquifer material, resulting in a decline in the amount of Ca^{2+} and Mg^{2+} in the groundwater and increase in the amount of Na^{+} in it. The opposite can take place when saltwater enters an aquifer, where some of the sodium in the saltwater is exchanged for calcium sorbed to the solid material of the aquifer (reverse ion exchange). The exchangeability of cations between aqueous and solid phases is governed by the strength of ions bond to the solid phase. Divalent ions bond more strongly to the solid phase than monovalent ions and, therefore are more difficult to exchange. The order of exchangeability of the major cations can be described as $Na^{+}>K^{+}>Mg^{2+}>Ca^{2+}$.

5. Oxidation-reduction (redox) reactions control the concentrations of nitrate (NO_3^-), manganese (Mn^{4+}), iron (Fe^{3+}) and sulphate (SO_4^{2-}) in groundwater. Redox reactions happen when electrons (e^-) are exchanged among solutes. They involve loss of electrons of certain elements (oxidation) which is associated with gain of electrons of other elements (reduction). For example, when iron dissolved in water that does not contain dissolved oxygen (DO) mixes with water that contains DO, the iron and oxygen interact by oxidation and reduction reactions. The result of such reactions is that the dissolved iron loses electrons (i.e. the iron is oxidised, Eq. 7-5) and the oxygen gains electrons (i.e. the oxygen is reduced, Eq. 7-6). The overall reaction is presented in Eq. 7-7. In this case, the iron is an electron donor and the oxygen is an electron acceptor.

$$Fe^{2+} \rightarrow Fe^{3+} + e^{-} \quad 7\text{–}5$$

$$H_2O_2 + 2e^{-} \rightarrow 2OH^{-} \quad 7\text{–}6$$

Overall equation:

$$2Fe^{2+} + H_2O_2 + 2H^{+} \rightarrow 2Fe^{3+} + 2H_2O \quad 7\text{–}7$$

Oxidation of iron will result in its precipitation because Fe^{3+} is much less soluble than Fe^{2+}. Iron occurs as Fe^{3+} in groundwater that contains DO of more than 1 mg/L, but it occurs as Fe^{2+} at lower DO concentrations. Iron (and manganese) dissolve more readily in oxygen–poor groundwater, especially if the groundwater is acidic (pH on the low side; <7).

Bacteria can use energy gained from redox reactions as they decompose organic material. This reduction process involves a sequence of electron acceptors consisting of O_2, NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, CO_2 and then methane (CH_4) fermentation products. This sequence is reversed during oxidation. So, the presence of products of redox reactions in groundwater can be used to identify the dominant type of such reactions in the aquifer. For example, the bacterial reduction of SO_4^{2-} to sulphide (HS^-) can result from oxidation of organic matter to CO_2. According to Edmunds and Shand (2008), a sequence of redox changes may be recognised along flow paths in aquifers. Hence, understanding redox conditions in a groundwater flow system can aid with hydrogeological conceptualisation and can provide additional evidence to help with the study of the system's hydrodynamics.

7.3 Material and methods

In this thesis, groundwater quality is investigated in order to supplement the understanding of the LMC groundwater system that is achieved from studying the area's geology, hydrology and hydrogeology. This undertaking involved reviewing previous hydrogeochemical studies (Section 1.6.2) and synthesis of water quality data available from Horizons Regional Council. Horizons collect groundwater quality data primarily to fulfil their State of the Environment (SoE) monitoring

responsibilities. However, the data they collect are also suitable for hydrochemical investigation purposes.

Hydrochemical interpretations undertaken in this research attempt to mine available data to reveal the processes that control the groundwater quality in the study area. Hence, the study is focused on the major inorganic constituents. Davis and DeWiest (1966) classified groundwater quality constituents based on their global average ranges as follows:

1. major constituents (1–1,000 mg/L)
2. secondary constituents (0.01–10 mg/L)
3. minor constituents (0.0001–0.1 mg/L)
4. trace constituents (<0.001 mg/L).

The study of major constituents and their ratios in groundwater enables identification of different water types (hydrogeochemical facies or groundwater masses). Interpolation of the spatial distribution of the concentrations of various parameters and hydrogeochemical facies can provide information on groundwater recharge and discharge areas, flow paths, aquifer conditions and the dynamics of groundwater quality evolution. Hydrochemical interpretations in this study have been mainly undertaking using maps and classical graphical methods.

Zarour *et al.* (2011) and PDP (2013a) list the groundwater quality parameters that Horizons monitor. They include:

1. Physiochemical field measurements: temperature, electrical conductivity (EC), pH, redox potential (Eh), dissolved oxygen (DO)
2. Major cations: calcium (Ca), magnesium (Mg), sodium (Na), potassium (K)
3. Major anions: alkalinity or bicarbonate (HCO_3), sulphate (SO_4), chloride (Cl)
4. Nutrients: nitrate (NO_3), nitrite (NO_2), ammonium (NH_4), phosphate (PO_4);
5. Parameters that often affect water supply quality: iron (Fe), manganese (Mn), arsenic (As)

6. Other indicative parameters: silica (SiO_2), fluoride (F), boron (B), bromide (Br)
7. Bacterial contamination indicator: *Escherichia coli* (*E. coli*).

7.4 Data availability

Data collected from the start of groundwater quality monitoring in the LMC until the end of 2007 had been obtained from Horizons Regional Council for this research. These data include 1,584 records relating to 631 wells in the LMC and within 2 km around it (Figure 7-1). The distribution of sampled wells shown in Figure 7-1 indicates reasonably good spatial coverage. However, there are no data from areas topographically higher than 160 masl. Sampled wells encompass a useful range of depth into the groundwater system (Figure 7-1 and Figure 7-2).

Post 2007 groundwater quality data are not readily available in useable form from Horizons Regional Council. For this reason and given the lack of trend noticed by previous studies and the abundance of pre-2007 data, this research has not attempted to use data collected after 2007.

Accurate sample collection data are missing. Anecdotes indicate that all samples are collected from non-dedicated, privately owned, operational bores. Monitored bores vary in design and the construction detail of some are not known. Samples are generally thought to have been collected after purging the bores of standing water by pumping the equivalent to three bore water volumes. It is believed that field measurements are only taken after monitoring of purged water shows they have stabilised.

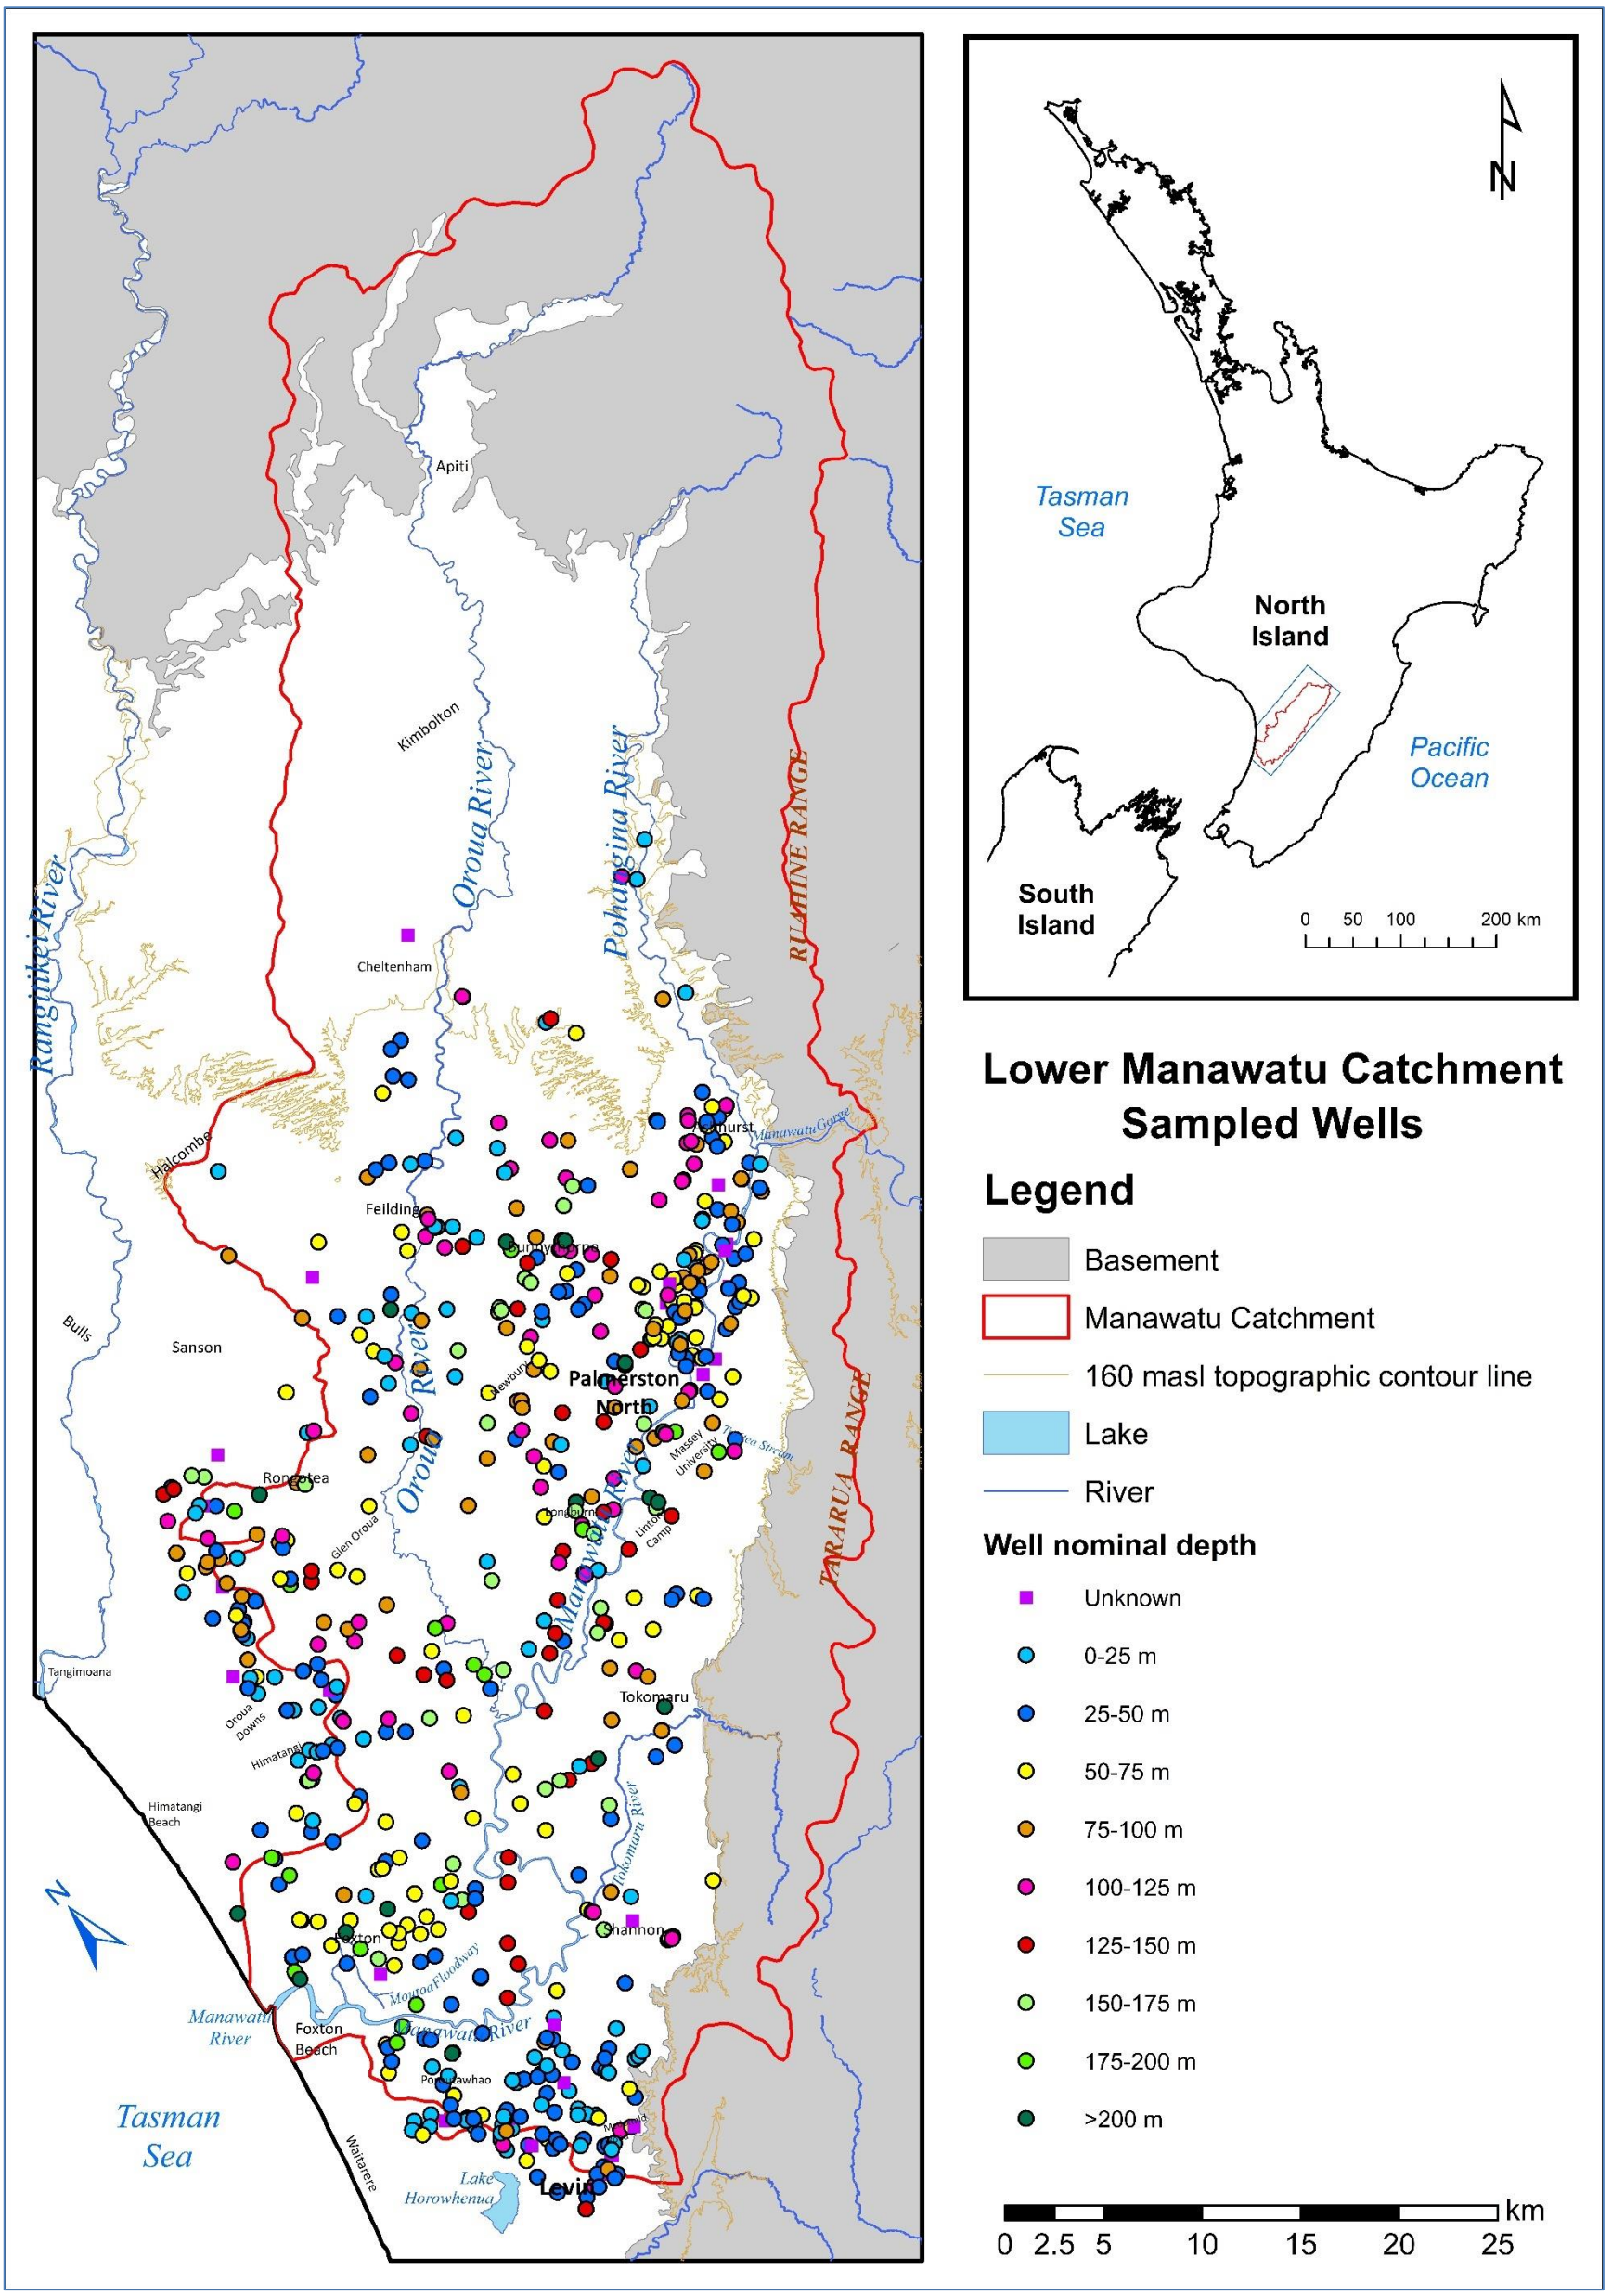

Figure 7-1. Location map showing groundwater quality sampling sites and depths in the LMC until the end of 2007.

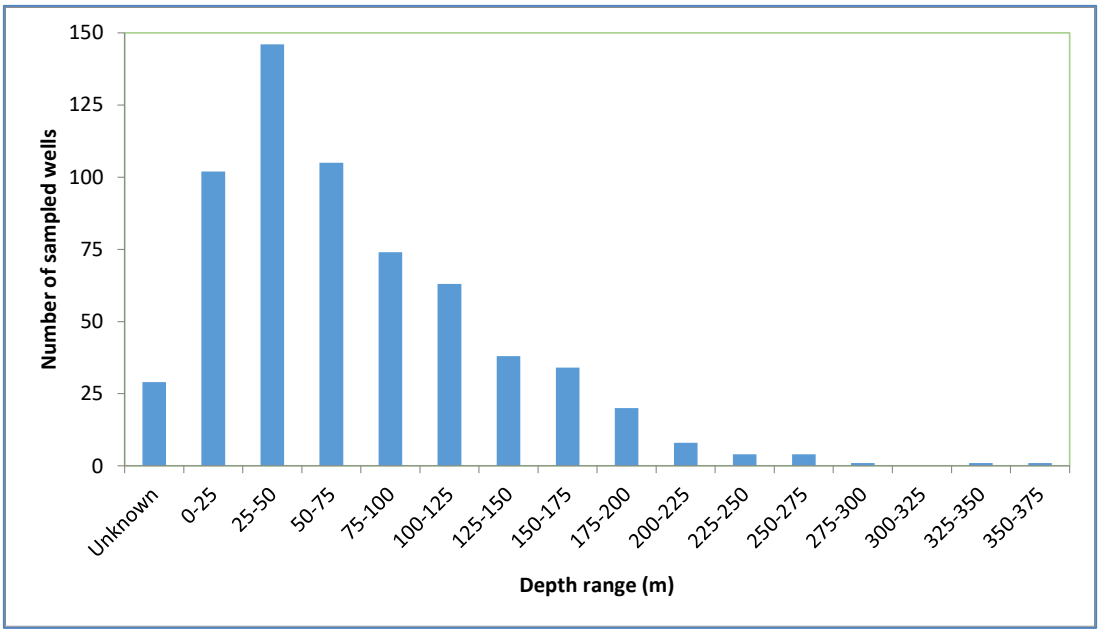

Figure 7-2. Depth range of sampled wells in the LMC.

All groundwater quality samples are thought to have been collected in three bottles, one for unprocessed water, another for filtered water, and the third for filtered and acid treated water. Information recorded during sampling include pre-sampling water level, site and weather conditions. Samples are stored in cooler boxes and couriered to laboratory overnight. Laboratory analyses are thought to be carried out according to the current edition at the time of analysis of the Standard Methods Examination of Water and Wastewater by the American Public Health Association and American Water Works Association and Water Environment Federation.

7.5 Data reliability

The relative abundance of hydrogeochemical data in the LMC enables interpretation to help understand the processes that control groundwater quality in the area and groundwater hydraulic conditions. However, the reliability of the data and their representativeness must also be examined before attempting any spatial interpolation of available hydrochemistry records.

7.5.1 Quality control (QC)

Water is electrically neutral, i.e. positive and negative charges in it are equal. Hence, laboratory analysis results are expected to present a balanced sum of cations and anions calculated in milliequivalent/litre (meq/L). Checking the cation–anion balance (CAB) in hydrogeochemical data is considered the first and foremost important quality control (QC) check of the goodness of the data. The United Nations Environment Programme (UNEP) and the World Health Organization (WHO) regard the ionic balance check as one of the basic tests of the quality of groundwater quality data, and recommend an upper acceptable limit of 5% to enable qualified interpretation of the data (Bartram & Ballance, 1996). However, CAB is perhaps one of the most confusingly defined parameters in groundwater sciences. Some workers define CAB as the ratio of the difference between the cations and anions to either sum (CAB_1 in Eq. 7–8) whereas others define it as the ratio of the difference between the cations and anions to their mean (CAB_2 in Eq. 7–9). In both Eq. 7–8 and Eq. 7–9, the sum of cations ($\sum Cations$) and sum of anions ($\sum Anions$) are taken as absolute values, i.e. neither negative nor positive. Comparing Eq. 7–8 and Eq. 7–9 provides that CAB_2 is double CAB_1. Noticeably, users of both equations implicitly agree on acceptable CAB limits for groundwater quality analysis data. Users of Eq. 7–8 normally set the acceptable CAB value range between −5% and 5% and users of Eq. 7–9 set the acceptable CAB value range between −10% and 10%. The two error limits are clearly identical. Anyway, one should be very careful with the way CAB is defined when dealing with data from various sources because, for example, accepting chemical analyses that have CAB up to 10% that is calculated using Eq. 7–8 will introduce serious interpretation errors.

$$CAB_1 = \left[\frac{\sum Cations - \sum Anions}{\sum Cations + \sum Anions}\right] \times 100\% \qquad 7\text{–}8$$

$$CAB_2 = \left[\frac{\sum Cations - \sum Anions)}{(\sum Cations + \sum Anions)/2}\right] \times 100\% \qquad 7\text{–}9$$

To avoid confusion in this thesis, Eq. 7-8 is adopted to calculate the cation-anion balance, which is simply termed CAB from this point onwards. Acceptable analysis in this thesis must have CAB values in the range of -5% and 5%.

Only major constituents are normally used in CAB calculations, namely calcium (Ca^{2+}), magnesium (Mg^{2+}), sodium (Na^{+}), bicarbonates or alkalinity (HCO_3^{-}), sulphate (SO_4^{2-}), and chloride (Cl^{-}). Occasionally, investigators consider potassium (K^{+}) to be a major cation and include it in CAB calculations.

A positive CAB value indicates missing anions and a negative CAB value implies missing cations. Zarour (2008) explains that large CAB is indicative of a laboratory error and/or overlooking analysis of one or more important constituents in the water sample. In both situations, the trustworthiness of the reported groundwater quality results is compromised. Accordingly, CAB can be used to check on the reliability of a chemical analysis.

7.5.2 Quality assurance (QA)

Zarour (2008) examined all groundwater quality data available in Horizons Regional Council database. He found that nearly half of the records are for incomplete analyses that do not include all major constituents, so the reliability of their laboratory analysis results cannot be assessed. He also found that around 30% of the samples pass the 5% CAB threshold whereas the remaining samples (20%) do not.

Table 7-1 summarises the CAB status of available hydrochemical data in the LMC until 2007. It shows that 28% of the available records are considered complete and pass the CAB test. These 446 records relate to 268 wells that are well distributed in the LMC below the 160 masl topographical contour line (Figure 7-3).

Table 7-1. Status of available groundwater quality records in and within 2 km of the Lower Manawatu Catchment until the end of 2007.

Analysis status	No. of samples	Percentage of total
Incomplete	1,093	69.00
Acceptable error	446	28.16
Unacceptable error	45	2.84
Total	**1,584**	**100.00**

The number of samples with unacceptable CAB amount to nearly 10% of the number of samples with acceptable CAB. This indicates that the laboratory results are generally good, which allows cautious use of data from incomplete analyses for hydrogeochemical interpolation purposes. Most of the incomplete analyses relate to samples that have been collected for a specific reason that did not require the analysis of all other constituents, e.g. nitrate monitoring. Overall, the available hydrogeochemical data represent a wealth of information that can be used effectively to enhance hydrogeological knowledge of the LMC groundwater system.

Table D-1 in Appendix D presents a list of all wells in the LMC that have complete, acceptable groundwater quality data up to the end of 2007, with brief data availability statistics. Table D-2 in the same appendix presents all groundwater quality records that were obtained from Horizons and found to be complete and acceptable for the purposes of this thesis.

Acceptable samples cover the area fairly well (Figure 7-3). The depth range coverage of these samples is also relatively satisfactory (Figure 7-4). Figure 7-5 presents a histogram of CAB values for samples analysed for all major constituents in the area. The histogram shows that it is more likely that anions exceed cations in samples. This may be related to laboratory accuracy, sample collection and handling methodology, or not analysing for certain cations.

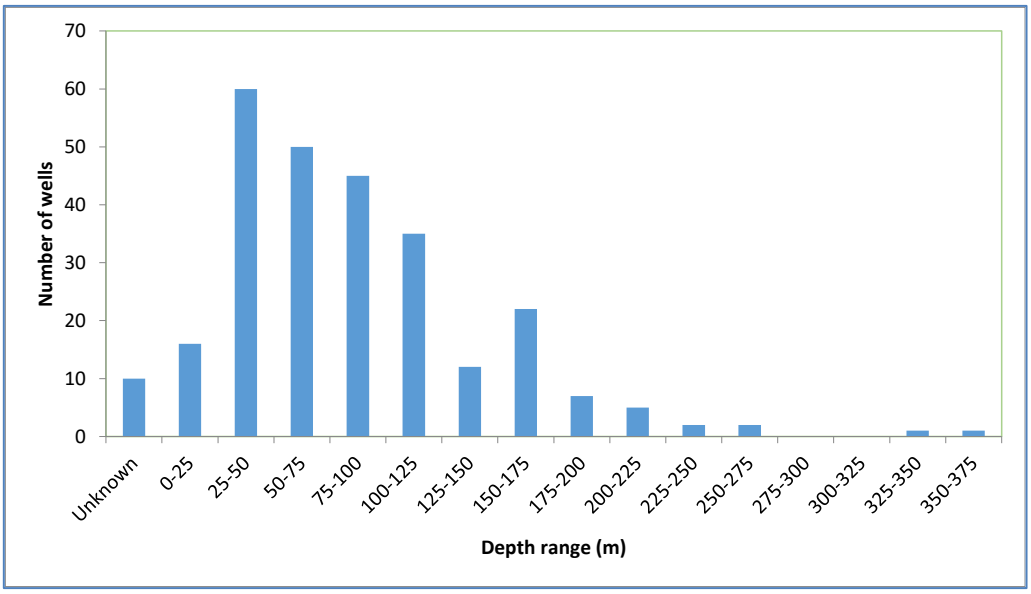

Figure 7-4. Depth range of wells with acceptable samples in the LMC.

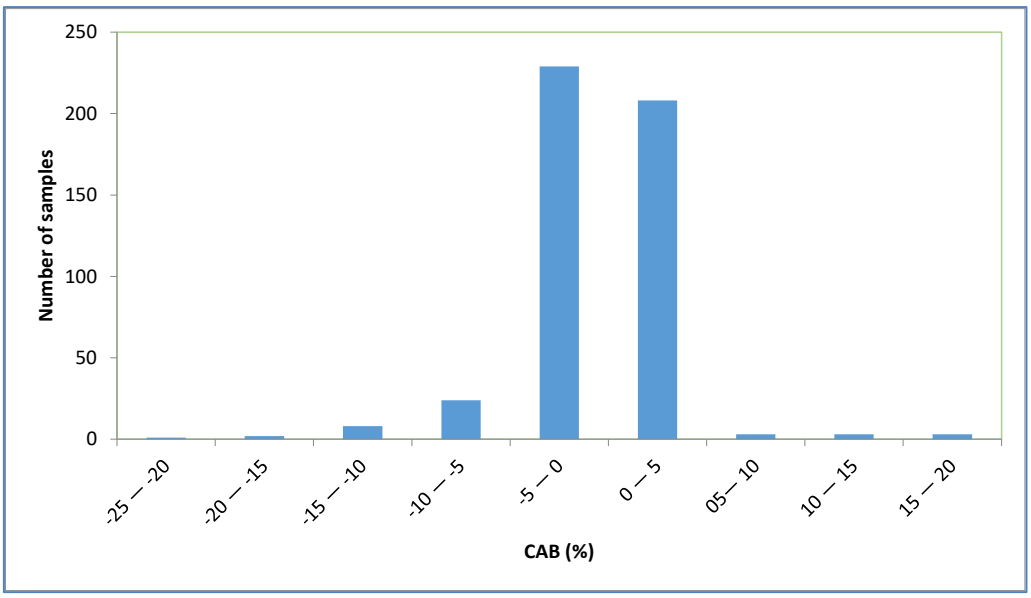

Figure 7-5. Frequency plot of CAB values for samples from LMC until the end of 2007.

7.6 Groundwater quality temporal variability

Seven wells in the LMC have reasonably long-term groundwater quality monitoring records until the end of 2007 (Appendix D). Table 7-2 lists such wells and presents information on their available groundwater quality records. Figure 7-6 shows the locations of these seven wells and Figure 7-7 through Figure 7-13 present groundwater quality time-series plots for them.

Table 7-2. Status of available groundwater quality records in and within 2 km of the Lower Manawatu Catchment until the end of 2007

Well	NZMG		Elevation	Well Nominal	Well Screens			All Samples			Acceptable Samples

The groundwater quality hydrographs (Figure 7-7 through Figure 7-13) support the interpretation of previous investigators who all agree that groundwater quality in the LMC neither exhibits strong seasonal variability nor entails noticeable temporal trends. Absence of significant trend in groundwater quality data is not only characteristic to the LMC, but is rather a commonplace phenomenon throughout New Zealand. Daughney and Wall (2007) statistically analysed groundwater quality data from 119 National Groundwater Monitoring Programme (NGMP) sites and 871 SoE monitoring sites throughout New Zealand. They reported that they did not detect any perceptible long-term trend in the country's groundwater quality. Two of the NGMP wells studied by Daughney and Wall (2007) are the LMC Wells 336113 and 354011 (Table 7-2, Figure 7-6, Figure 7-8 and Figure 7-13).

7.7 Representative samples

To maximise the possibilities for hydrogeochemical interpretation, representative samples for the largest possible number of wells are needed to provide greatest areal and depth range coverage. The well-established lack of notable seasonal and temporal variability in the area's groundwater quality means that it is feasible to use data collected from different wells at different times for catchment-scale

interpretation. If a well has only one complete/acceptable sample, that sample is considered representative to that well unless proven an outlier during further data synthesis. If a well has more than one complete/acceptable sample, the sample with the smallest CAB value is taken to represent it unless proven an outlier by subsequent processing. Hence, a representative sample has been assigned to each of the 268 wells shown in Figure 7-3. Table D-2 in Appendix D specifies which samples are considered representative to the area's wells. The date of the representative sample for each of the wells that have long-term groundwater quality record is shown on the groundwater quality hydrograph for that well (Figure 7-7 through Figure 7-13).

7.8 Hydrogeochemical facies (multi-ion ratios and water types)

The notion of hydrogeochemical facies was developed in analogy with the concept of geological facies (Schumacher, 1999). It is a diagnostic method to determine the chemical character of water in hydrogeological systems based on the ratios between major dissolved ions. Hence, it provides a convenient means to subdivide water masses based on their major constituents into special categories that reflect the hydrogeochemical processes and controls in the groundwater system (Nwankwoala & Udom, 2011). Graphical methods have been conveniently used for hydrogeochemical facies classification (e.g. Durov, 1948; Piper, 1944). Ion ratios and hydrogeochemical facies plots require concentrations to be expressed in milliequivalent per litre (meq/L) units.

More recently, researchers have been increasingly utilising Hierarchical Cluster Analysis (HCA) in hydrogeochemical assessments (e.g. Daughney *et al.*, 2009). However, hydrogeochemical facies methods are preferred to HCA as the latter does not consider hydrogeochemical processes and conditions, but rather depends on fuzzy logic to relate water quality statistics to hydrogeology.

A number of previous groundwater studies in the LMC utilised ion ratio plots and the well-known Piper and Durov diagrams (e.g. Mark-Brown, 1978; Schumacher, 1999; Zarour, 2008). According to Younger (2007), the Durov diagram is similar to

the Piper Diagram (Figure 1-3) but it produces clearer output that is especially well-suited to deducing the processes contributing to the chemical evolution of groundwaters in a given flow system. The Piper Diagram has a diamond-shaped centre area and requires the calculation of the percentages of individual ions to be determined as percentages of the separate totals of cations and anions. The Durov Diagram has a squared centre area and the percentages of individual ions used in it are calculated as percentages of total ions. Both diagrams are well-suited for fresh groundwater hydrogeochemical interpretation (Younger, 2007). An Expanded Durov Diagram was introduced by Burdon and Mazloum (1958) and Lloyd (1965). It has the advantage of being able to classify groundwater into very distinct fields that correspond to specific hydrogeochemical conditions. The procedure for plotting the Expanded Durov Diagram is illustrated in (Figure 7-14). Lloyd and Heathcote (1985) and Younger (2007) describe how to interpret data using the Expanded Durov Diagram (Figure 7-15).

Plotting trilinear diagrams is a tedious process, which has been facilitated by software packages that enable easy production of the Piper and Durov diagrams. There has not been a package to produce the much more laborious Expanded Durov Diagram until Al-Bassam *et al.* (1997) presented DurovPlot©. However, it was difficult to obtain this DOS-based programme and it was not possible to run it on computers operating on modern versions of Microsoft Windows©. Therefore, the method has not been widely used. Al-Bassam and Khalil (2012) released DurovPwin©, which can plot up to 100 samples on the Expanded Durov Diagrams at a time. Aided with DurovPwin©, this thesis utilises the Expanded Durov Diagram in hydrogeochemical facies classification.

Because DurovPwin© has a 100-sample limit which, representative groundwater samples were plotted on the Expanded Durov Diagram in three continued drawings (Figure 7-16, p 209-211). Figure 7-17 shows the areal distribution of various groundwater facies across the LMC.

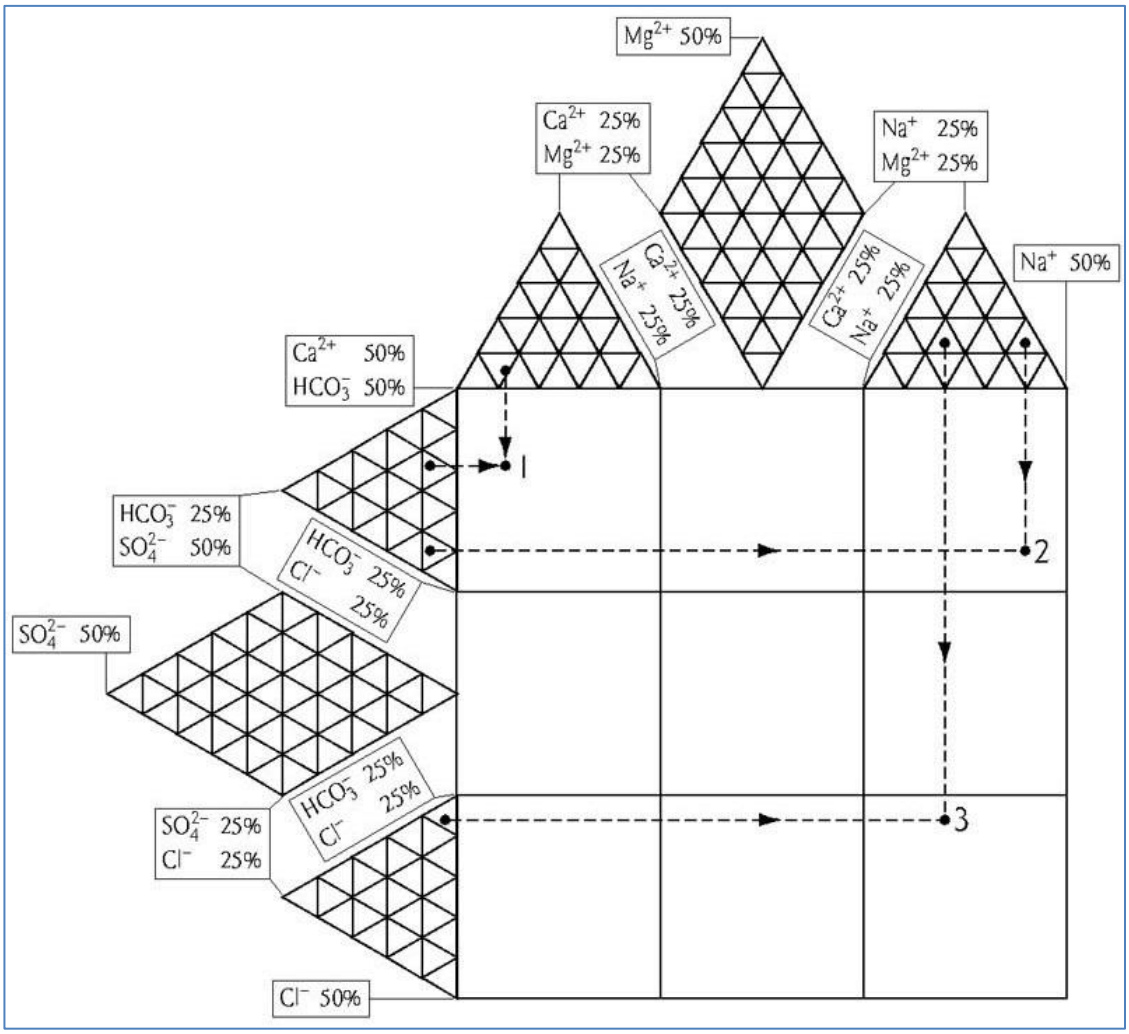

Figure 7-14. Procedure to plot samples on the Expanded Durov Diagram (adapted after Younger, 2007).

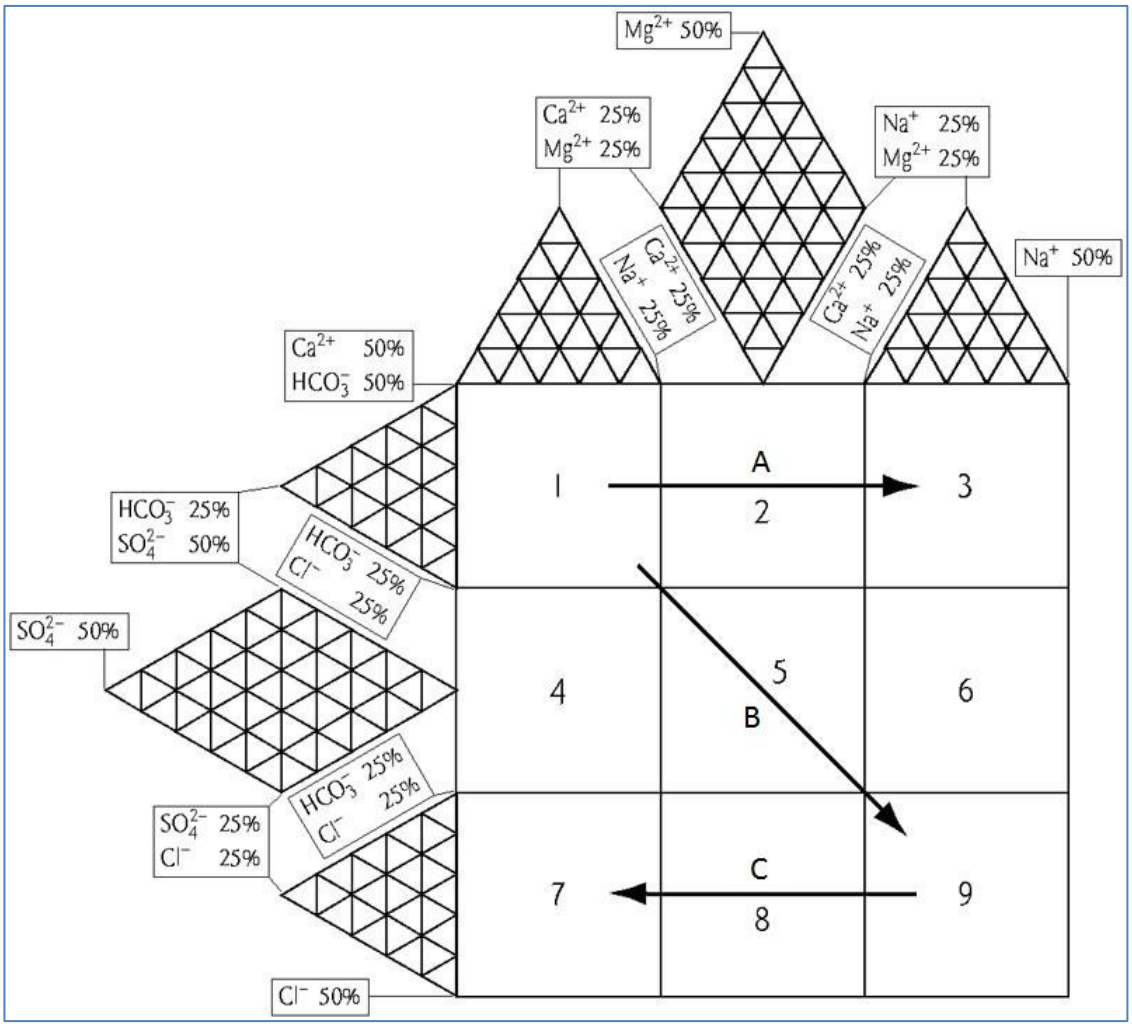

Figure 7-15. Interpolation of the Expanded Durov Diagram (Modified after Younger, 2007).

Field numbers can be used to typify the water and labelled arrows indicate evaluation processes for samples on the same flow path (A: ion exchange, B: dissolution and/or mixing, C: reverse ion exchange).

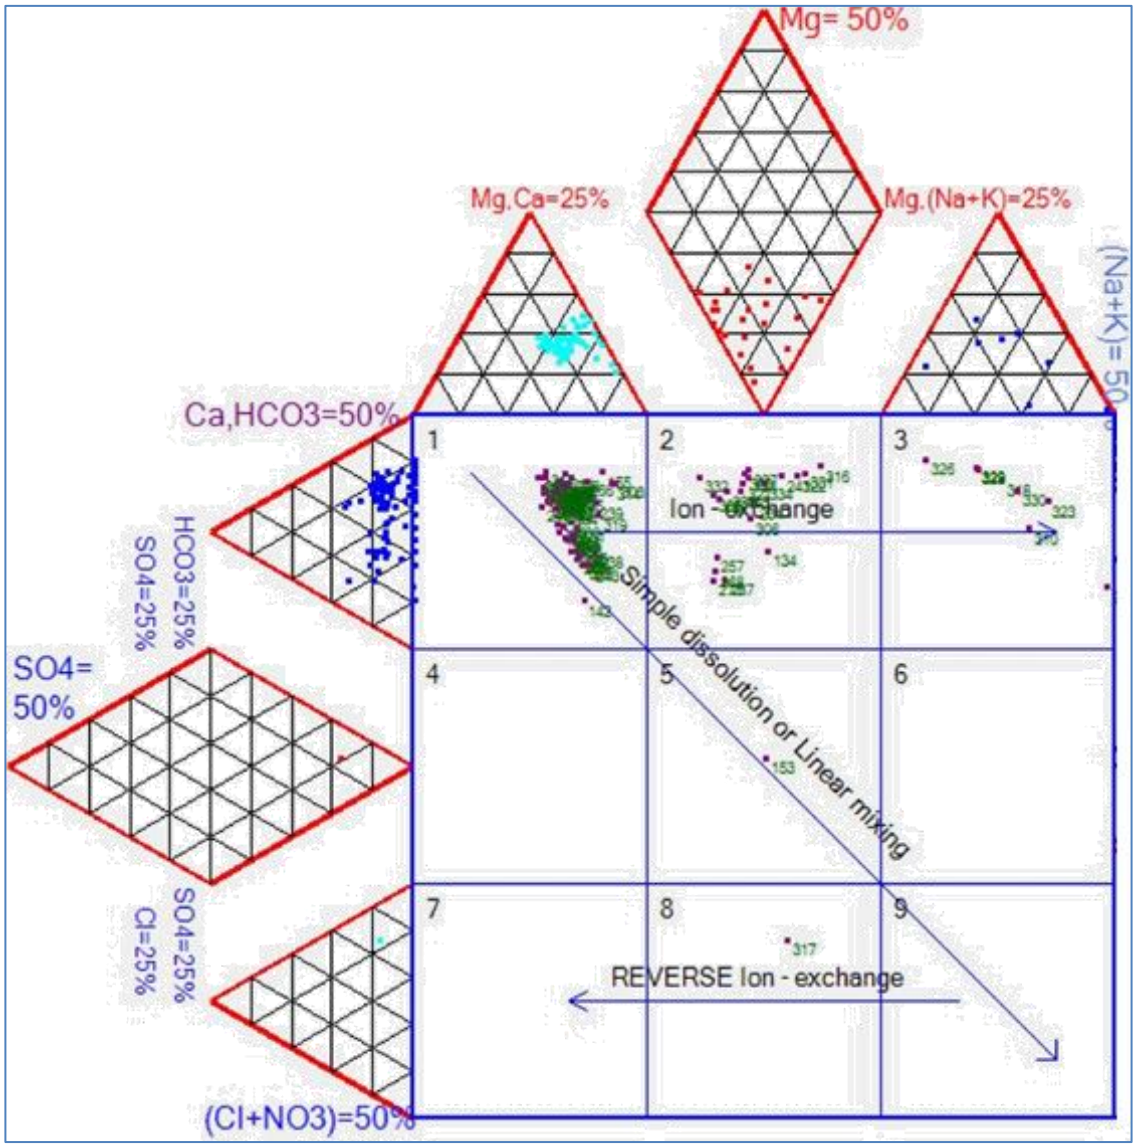

Figure 7-16 (cont.). Expanded Durov plot of samples from the LMC (continued overleaf).

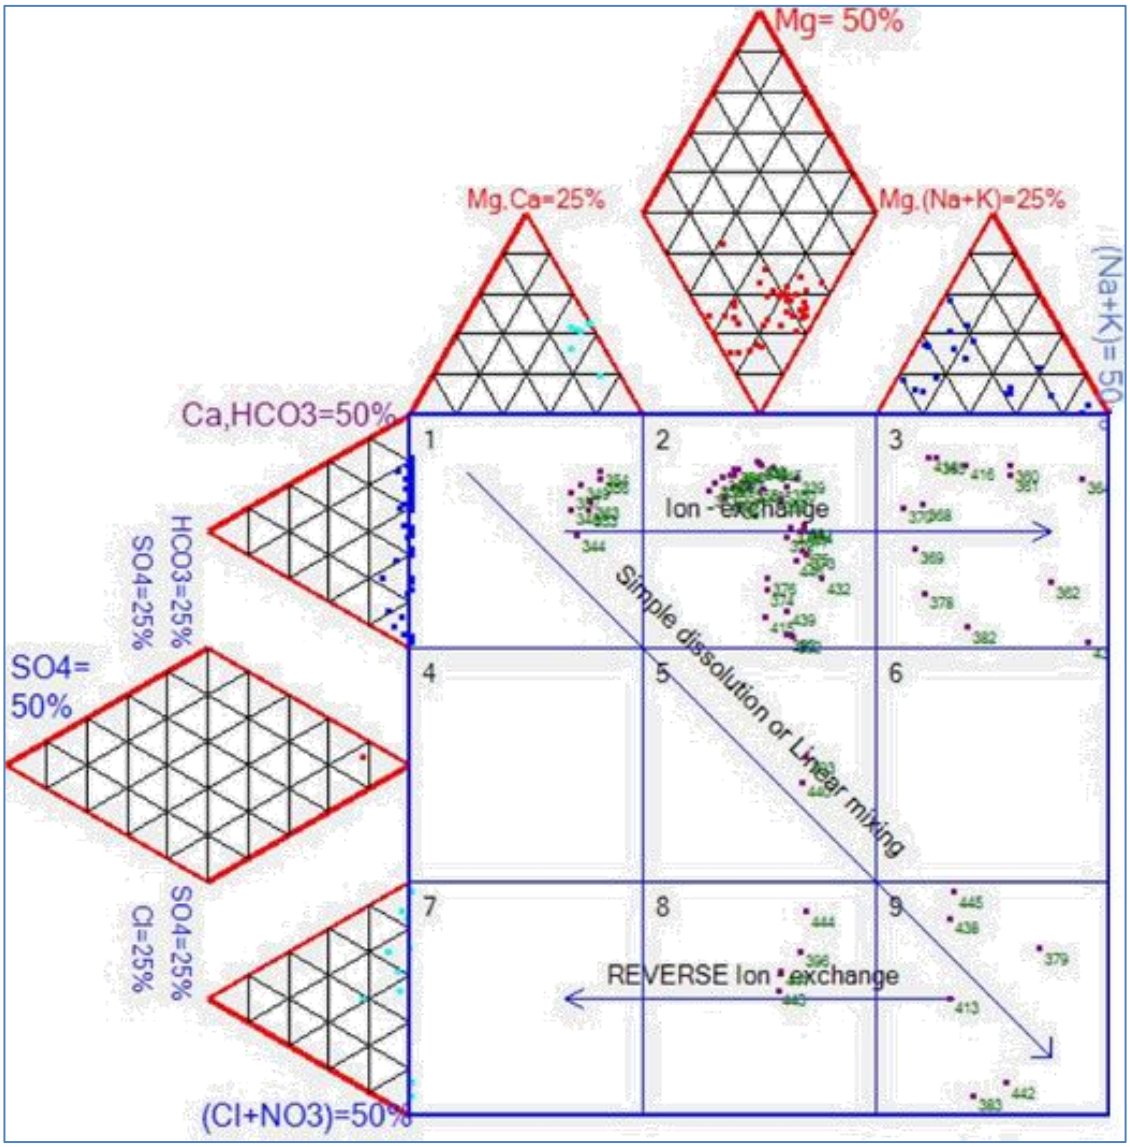

Figure 7-16 (cont.). Expanded Durov plot of samples from the LMC.

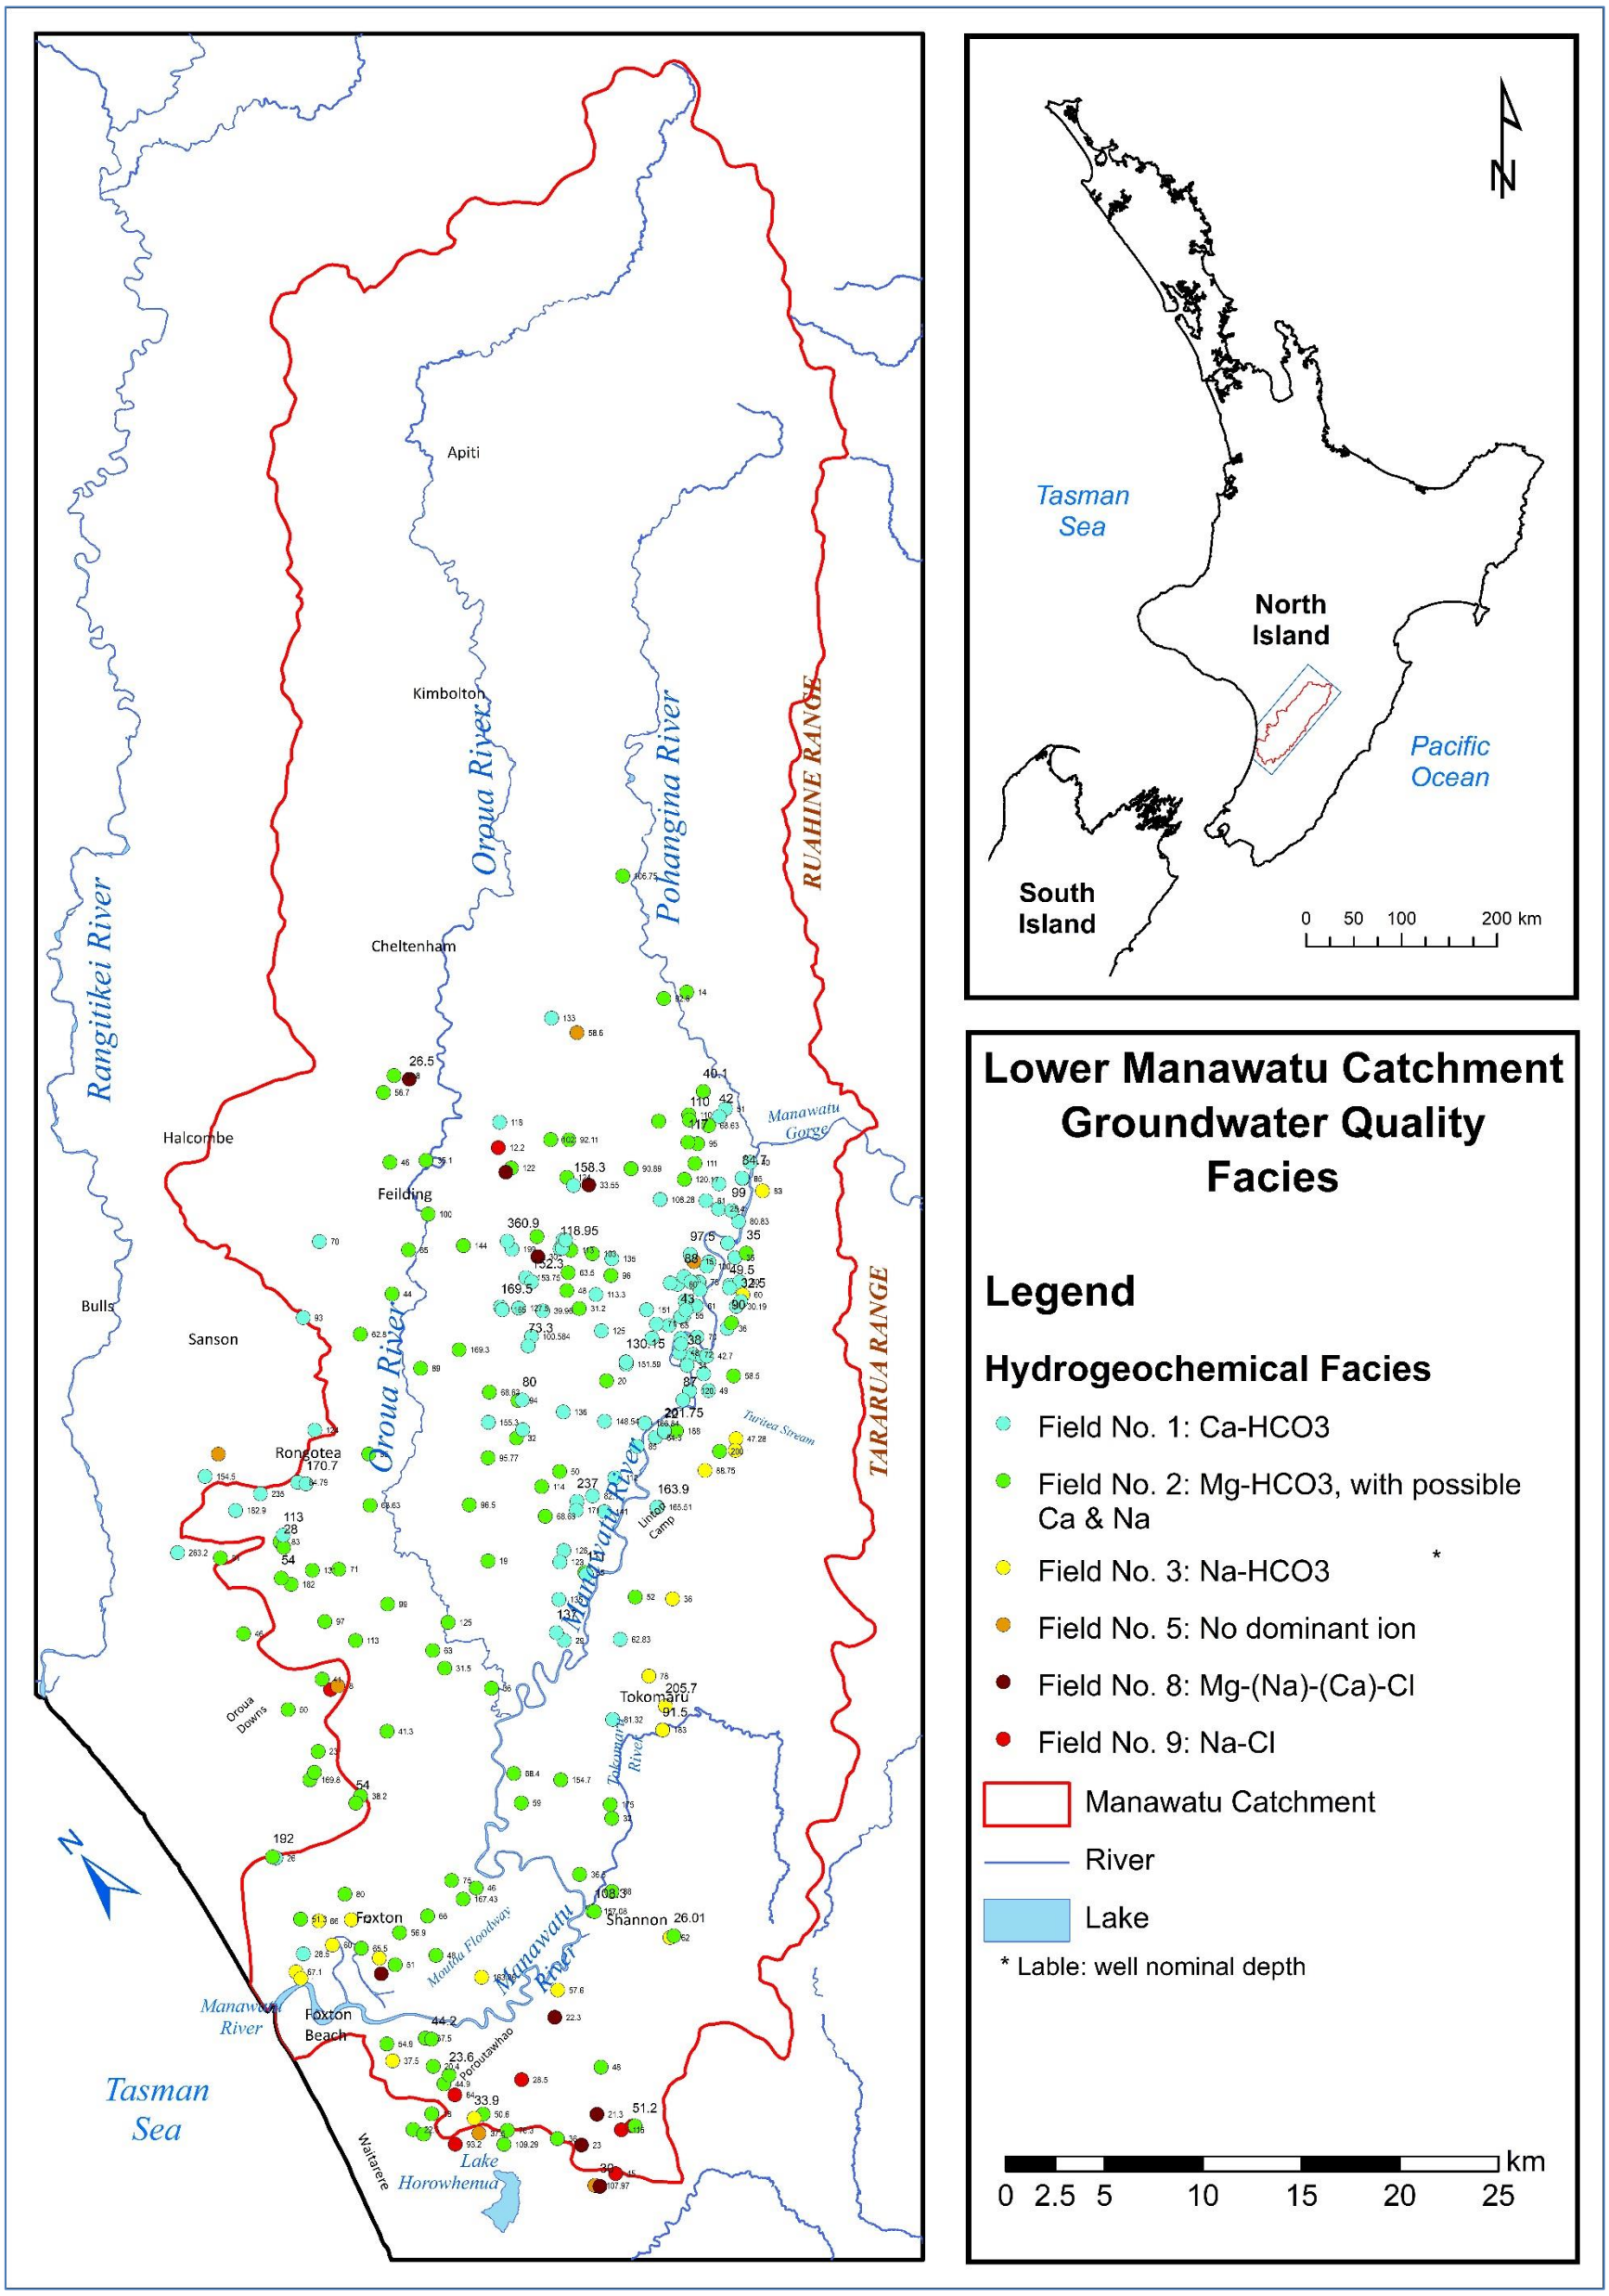

Figure 7-17. Groundwater quality types in the LMC.

The main characteristics and possible interpretation of the groundwater facies identified using the Expanded Durov Diagram are summarised in Table 7-3.

Table 7-3. Classification of LMC representative samples using the Expanded Durov Diagram hydrogeochemical facies typifying.
Interpretation is based on Lloyd and Heathcote (1985) and Younger (2007).

Field number	Predominant facies[47]	Possible interpretation	Number of samples
1	$Ca - HCO_3$	Fresh groundwater in recharge area.	111
2	$Mg - HCO_3$	Important proportions of Ca^{2+} and Na^{+} indicative of ion exchange.	113
3	$Na - HCO_3$	Unconfined aquifer or shallower portion of a regional-scale confined aquifer. HCO_3^- possibly resulting from dissolution of CO_2 generated at depth. Na^{+} is dominant due to ion exchange, dissolution of plagioclase or dilution of mineralised geothermal groundwater.	21
5	$No\ clear\ facies$	Normally the result of mixing of two or more different facies or indicative of waters exhibiting simple dissolution	6
8	$Mg - (Na) - (Ca) - Cl$	Mixing of fresh and saline waters. Possible influence of reverse ion exchange.	9
9	$Na - Cl$	Influence of seawater, ancient saline groundwaters, or dissolution of halite $(NaCl)$[48] frequently indicating end-point waters (e.g. seawater).	8

Figure 7-17 indicates that Expanded Durov diagram Field No. 1 $Ca - HCO_3$ facies is dominantly characteristic of groundwater in the Lower Manawatu Valley, from Ashhurst to the confluence of the Manawatu River with Oroua River (Figure 7-17). It reflects dominance of alkali earth and weak acids in the groundwater and may indicate local recharge from rain and/or river water. This hydrogeochemical facies is also found in the area between Taonui Stream and Manawatu River, to the southwest of Bunnythorpe and in the groundwater divide area associated with the Mt Stewart-Halcombe anticlinal structure. Coincidence of $Ca - HCO_3$ water with topographical highs and groundwater divides commonly signifies recharge area settings.

[47] It may be necessary to refer to the raw data to determine the precise facies in some cases.
[48] Discrimination between these various alternatives requires further analysis, such as plotting a Hounslow diagram.

Expanded Durov diagram Field No. 2 $Mg - HCO_3$ water facies is widespread across the LMC (Figure 7–17). It represents recharge water that had the chance to evolve further than Field No. 1 water masses. Important proportions of Ca^{2+} and Na^{+} in these waters indicate noticeable ion exchange. In coastal settings, this water type is generally typical of the 'leading–edge' of seawater intrusion into a shallow unconfined aquifer. However, this is not the case in the LMC as groundwater of this type is not excessively saline and the water type is fresh in the coastal area.

Expanded Durov diagram Field No. 3 $Na - HCO_3$ water type seems to be associated with Last Interglacial deposits, but also is found in the Foxton area (Figure 7–17). $Na - HCO_3$ facies possibly indicates ion exchange resulting from slower flow rates and longer interaction between groundwater and the aquifer material. According to Herczeg *et al.* (1991), the release of Na^{+} into dilute waters nearer the recharge areas may be accomplished by: (a) dissolution of Na^{+}–bearing minerals (e.g. plagioclase or orthoclase), (b) cation exchange that releases Na^{+} from clay minerals, (c) conversion of a Na^{+}–smectite to kaolinite. Incongruent dissolution of albite releases Na^{+} and HCO_3^{-} into solution in an approximately 1:1 ratio, which clearly is not the case in the LMC (Figure 7–18). $Na - HCO_3$ water type may also indicate the generation of CO_2 at depth in a Na^{+} dominated environment (Chadha, 1999). Dominant Na^{+} can result from the dissolution of plagioclase in greywacke and greywacke–derived sediments and the dilution of mineralised geothermal groundwater. The warmest groundwater in the LMC (c. 20°C) is tapped by the nearly 200 m deep Wells 336233 and 336442 located at Massey University Turitea Campus. There is also anecdotal evidence that deep wells at Linton Military produce even warmer water. At such depths, it is unlikely that the groundwater temperature is a result of thermal pollution to the aquifer from the university or the army camp. It is more likely to be related to mineralised geothermal water emerging from the nearby basement rock, which mixes with groundwater affecting its physical and hydrogeochemical properties.

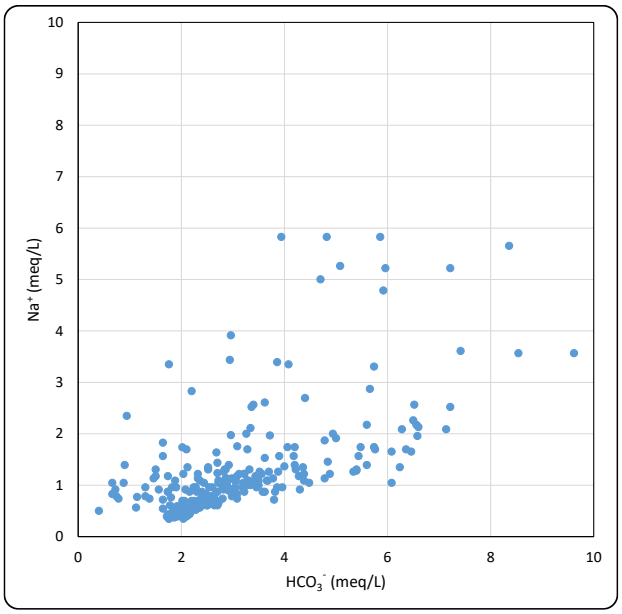

Figure 7-18. HCO_3^-:Na^+ relationship for LMC groundwater.

Field No. 3 water type is also found in the Foxton area, near the terminus of the Manawatu River and LMC groundwater system into the Tasman Sea (Figure 7-17). In the absence of elevated Cl^- levels, the source of Na^+ in that area is likely to be ion exchange rather than seawater invasion or sea spray. In some cases where ion exchange is a predominant process, high Na^+ can remain in groundwater after the flushing of Cl^-.

There are only few samples representing Expanded Durov diagram Field No. 5 water type, mainly located at marginal settings, e.g. very close to the groundwater divide (Figure 7-17). The sample of this type found near Te Matai Road could also be considered $Ca - HCO_3$ water facies (Field No. 1), despite technically falling in Field No. 5 on the Expanded Durov diagram. There is also a Field No. 5 sample that relates to a nearly 56 m deep well on the crest of the Pohangina Anticline. This sample has high proportions of Na^+, Mg^{2+} and Cl^-, which may reflect effects of local land use practices on the groundwater resource. However, this effect is not widespread as evidenced by data from neighbouring wells.

Expanded Durov diagram Field No. 8 $Mg - (Na) - (Ca) - Cl$ water type and Field No. 9 $Na - Cl$ water type are found preliminarily in the Poroutawhao Basement High

area, close to the southwestern boundary of the LMC (Figure 7-17). These water types are also found in the Bunnythorpe area and the area north of it. Field No. 8 water type is probably a mix of fresh groundwater and greywacke connate water that has undergone reverse ion exchange. Field No. 9 groundwater is believed to be connate waters from the greywacke basement high and overlaying deposits like the Plio-Pleistocene marine rocks in the Bunnythorpe area and the Last Interglacial strata near Levin.

7.9 Alkalinity and hardness

Groundwater in the LMC generally has low-moderate salinity (TDS<1,000 mg/L) and is mostly slightly alkaline (7.0<pH<8.5). In waters with pH not exceeding 9, alkalinity mostly consists of HCO_3^-. The areal distribution of pH values unsurprisingly suggests that acidic waters are present in recharge areas and alkaline waters are found in discharge zone settings (Figure 7-19).

Ca^{2+} and Mg^{2+} are the dominant cations in groundwater in the LMC (Figure 7-16 and Figure 7-17). Ca^{2+} and Mg^{2+} are mostly sourced from carbonate minerals. Miller (1952) clarifies that the solubility of $CaCO_3$ (e.g. calcite and aragonite) in water depends on the presence of CO_2, the concentration of which is a function of temperature and CO_2 pressure in equilibrium with the water. At fixed temperature, the solubility of $CaCO_3$ increases as CO_2 pressure increases. At constant CO_2 pressure, $CaCO_3$ solubility increases with decreasing temperature. CO_2 pressure is conveniently expressed as CO_2 partial pressure (pCO_2). Macpherson (2009) developed equation 7-10 to calculate partial pressure of CO_2 (pCO_2) from alkalinity (HCO_3^-) and pH.

$$log_{10}(pCO_2) = log_{10}(HCO_3^-) - pH + 7.749 \qquad 7\text{-}10$$

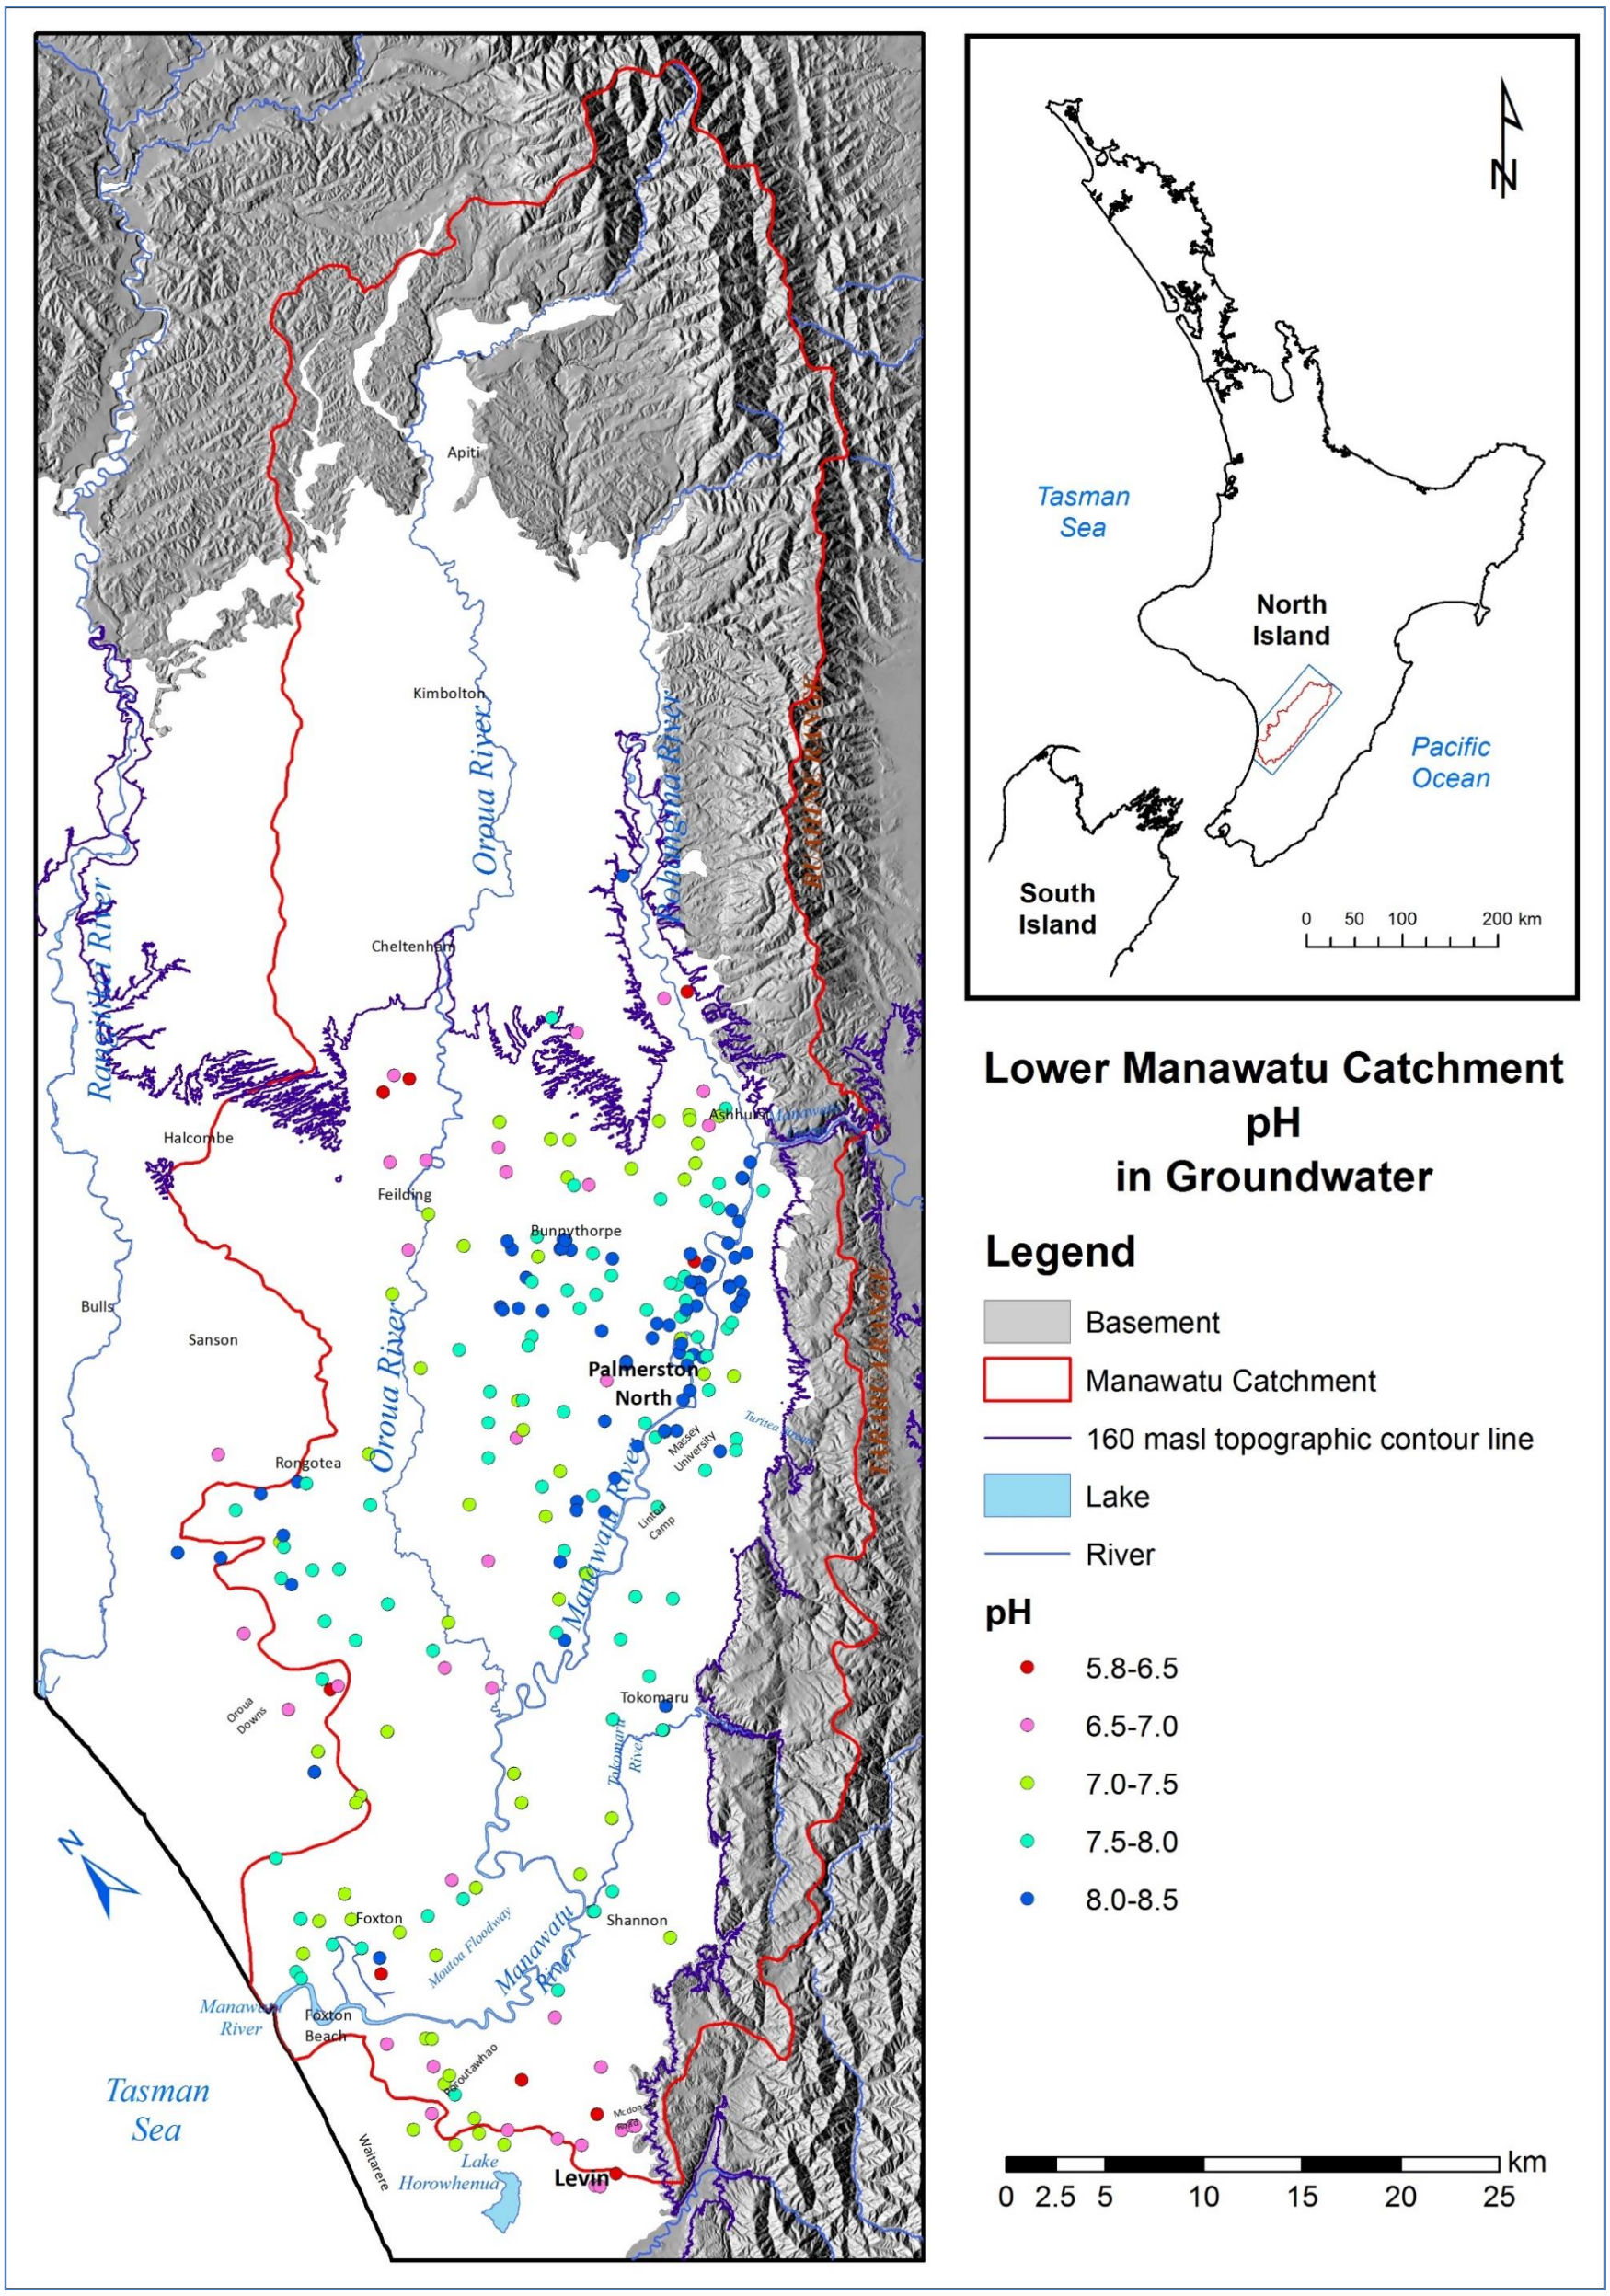

Figure 7-19. pH values for representative groundwater samples in LMC.

Equation 7-10 was used to calculate pCO_2 for representative samples from the LMC (Table D-3 in Appendix D). Global average for pCO_2 in the atmosphere is approximately 3.95x10^{-4} atm[49] (Atkins *et al.*, 2013). Table D-3 in Appendix D shows that pCO_2 in LMC groundwaters ranges between 3.96x10^{-3} and 8.23x10^{-1} atm, which is much higher than atmospheric values. This indicates that LMC groundwater is CO_2-enriched, which is consistent with drillers' anecdotal observation of 'gas' release occasionally noticed during drilling in the LMC. Irrigation with CO_2-enriched water such as the LMC groundwater may also result in CO_2 degassing, but this is not easily quantifiable (Macpherson, 2009). To check on the applicability of equation 7-10 to LMC conditions, calculated pCO_2 values have been plotted against measured CO_2 values (Figure 7-20). The linear relationship shown in Figure 7-20 gives confidence in both pCO_2 calculations and CO_2 laboratory results. The good correlation also suggests that the parameters used in pCO_2 calculations are reliable, namely HCO_3^- and pH.

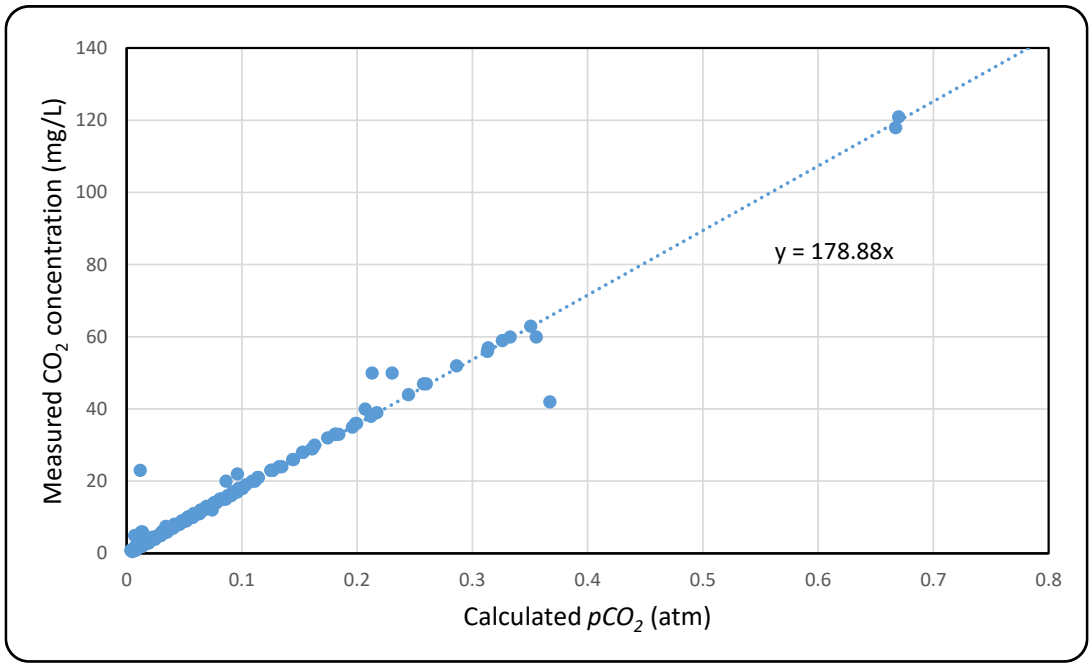

Figure 7-20. Relationship between calculated pCO_2 and measured CO_2 values in LMC groundwaters.

[49] 1 atm = 101.325 kPa

Co-existence of alkalinity (HCO_3^-) and bivalent cations such as Ca^{2+} and Mg^{2+} results in hardness, which is a cationic phenomenon. Hardness is a water use nuisance. It is normally expressed in units of mg/L as $CaCO_3$. When total hardness is less than alkalinity, all the hardness is due to carbonate. When total hardness exceeds carbonate hardness, the balance is non-carbonate hardness. Total, carbonate and non-carbonate hardness values for representative samples from the LMC have been calculated using USGS[50] PHREEQC© geochemical speciation and thermodynamics modelling code (Parkhurst & Appelo, 2013), which is incorporated in AquaChem© software (Table D-3 in Appendix D).

From the above data, it is clear that high CO_2 content and pressure in the LMC aquifer system is responsible for making HCO_3^-, Ca^{2+} and Mg^{2+} dominant in the area's groundwater. CO_2-enriched groundwater environments comprise shallow unconfined aquifers that are in contact with the high CO_2 soil zone and deep groundwater that is supplied with CO_2 from decomposition of organic matter such as peat.

7.10 Redox conditions and nitrate concentrations

Redox potential (Eh) is a measure of the tendency of a chemical species to accept electrons, i.e. to be reduced. It is expressed in volt (V) or millivolt (mV) units. Every species has its own intrinsic reduction potential. The more positive the species intrinsic reduction potential, the greater its affinity for electrons and tendency to be reduced. Positive Eh values indicate environments that favour oxidation reaction (e.g. free oxygen-rich systems) and negative Eh values characterise reducing environments (e.g. free metals-rich systems). Groundwater redox status is determined by the aquifer material composition, the relative rates of introduction of oxidants (e.g. O_2, CO_2 and NO_3^-) and the consumption of these oxidants by bacterially catalysed decomposition of organic matter (Rissmann, 2011).

[50] USGS: United States Geological Survey.

No Eh data are available to enable depiction of the redox status for the LMC groundwater system. Only very few measurements are available for dissolved oxygen (DO), iron and manganese species (Fe^{2+}, Fe^{3+}, Mn^{4+}, Mn^{3+}) to assist with standard quantitative analysis. Nevertheless, the system's redox situation can be assessed using other available hydrogeochemical data.

Examination of the redox category of the 268 representative groundwater samples using AquaChem© software reveals that only 18 wells tap 'weakly oxidised' groundwater, being water containing nitrate and sulphate, but no or very little oxygen and iron. All the remaining samples represent groundwater that is characterised by a 'redox conflict' as they contain strongly reduced and highly oxidised constituents. This is rather dissimilar to the opinion of previous investigators who believed that reduced conditions prevail in the LMC aquifers. Table D-3 in Appendix D shows that both 'weakly oxidised' and 'redox conflict' water types can occur at any depth in the LMC. However, 'weakly oxidised' groundwaters are more likely to be found at the southwestern boundary of the LMC, where Plio-Pleistocene strata may be thinner near the Poroutawhao Basement High (Figure 7-21).

Peat is abundant in the stratigraphy of the LMC (Figure 7-22). Its release of CO_2 is responsible for the LMC being dominated by HCO_3^-, Ca^{2+} and Mg^{2+}. CO_2 is released from the organic material (peat) in the aquifer stratigraphy into groundwater through fermentation of organic matter (see Section 7.9 for equations), which only occurs when all external electron acceptors have been used in accordance with the redox ladder or sequence (Figure 7-23). This process, which is known as methanogenesis involves production of methane (CH_4) as well as production and consumption of CO_2.

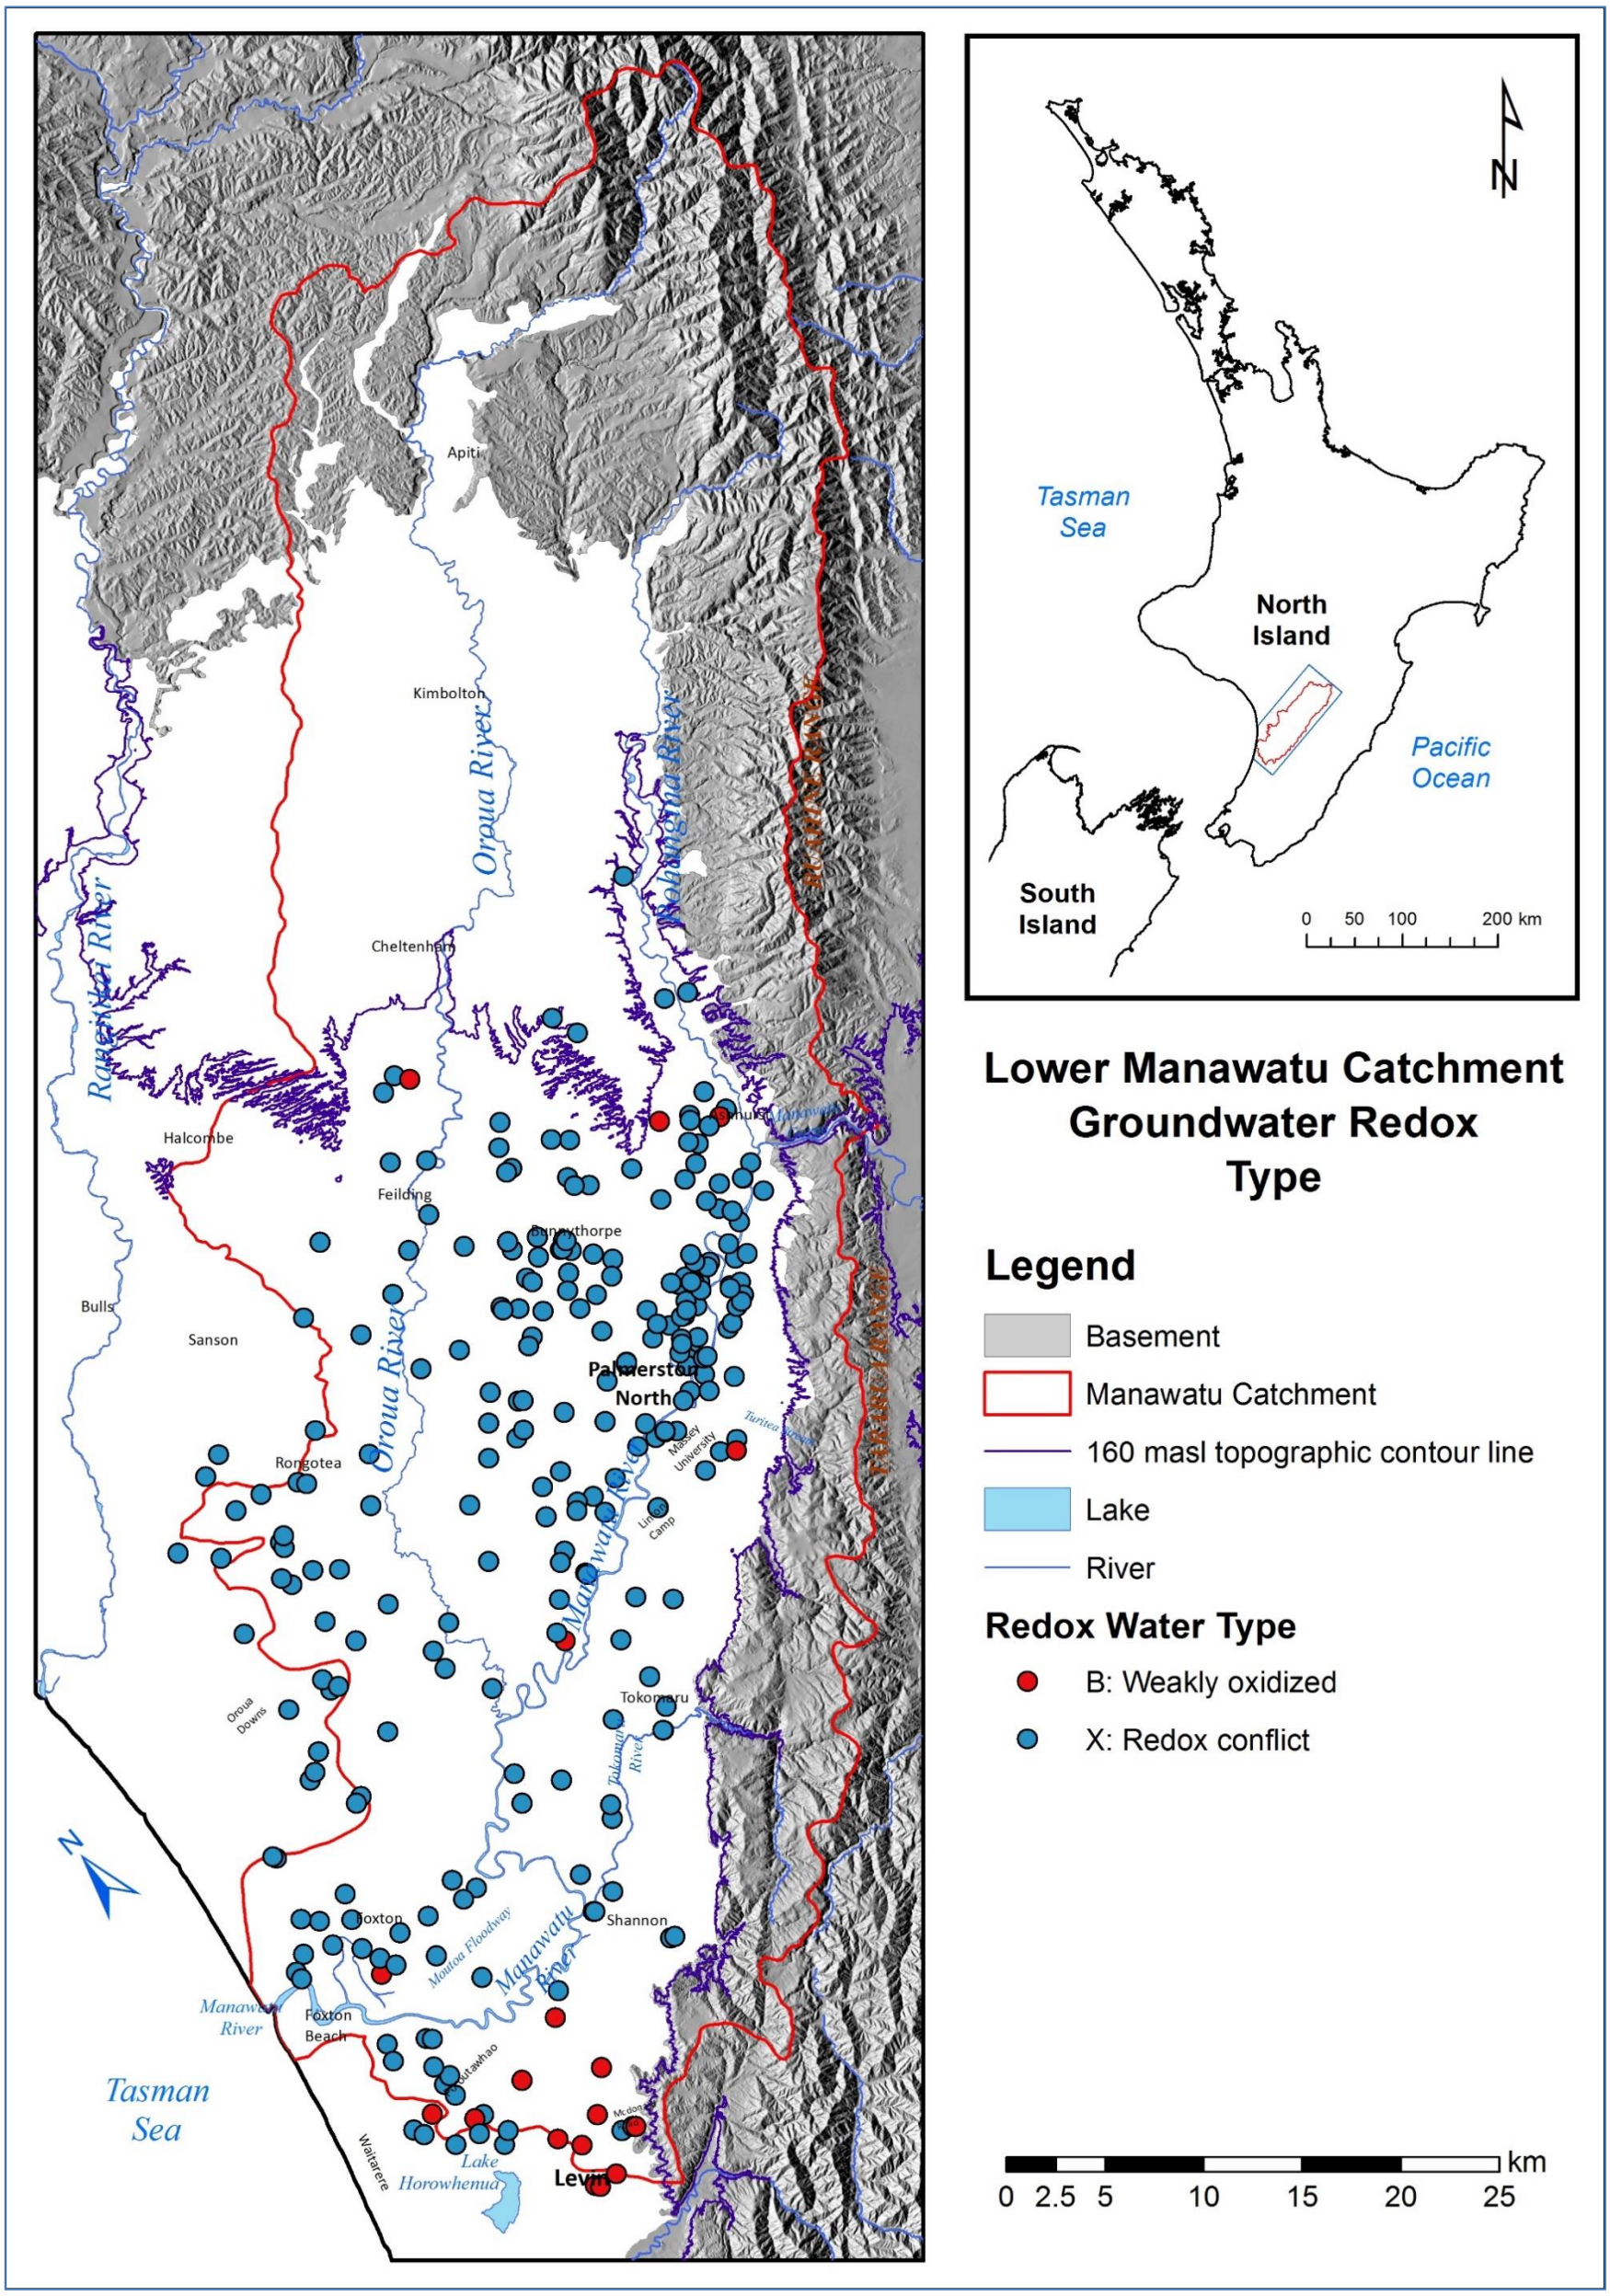

Figure 7-21. Redox groundwater types in the LMC.

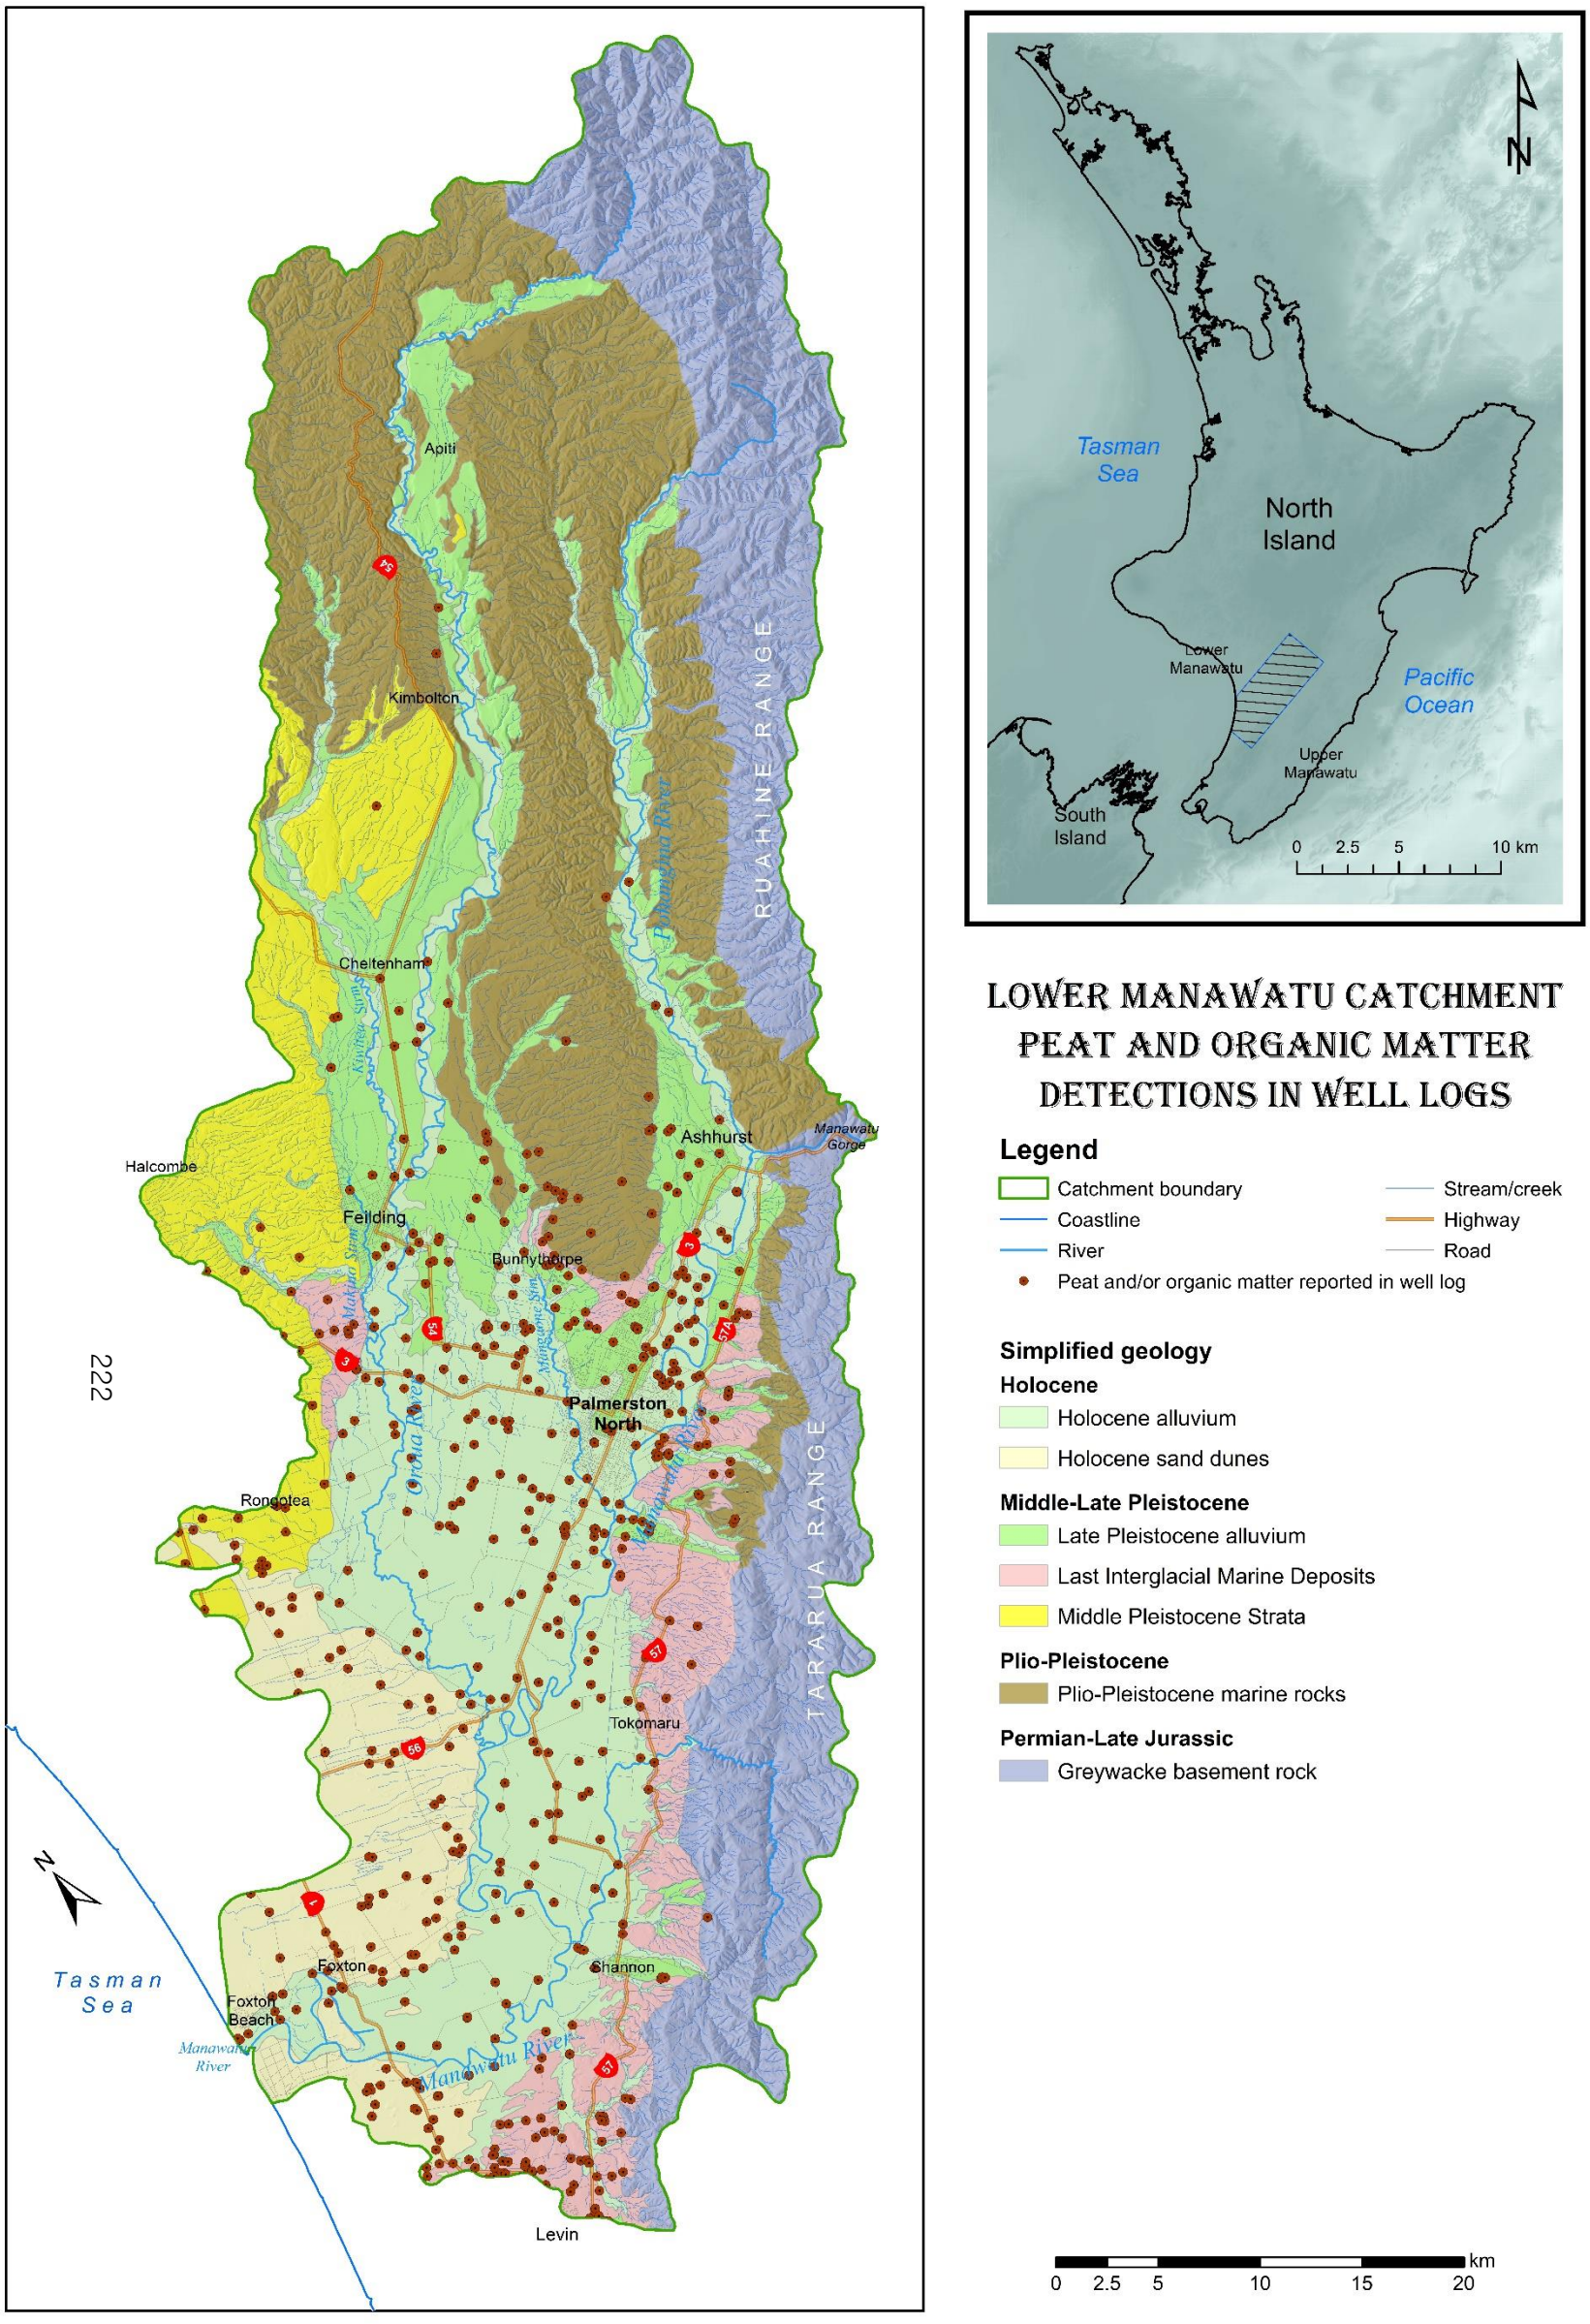

Figure 7-22. Location map showing detections of peat/organic matter reported in drillers' well logs.

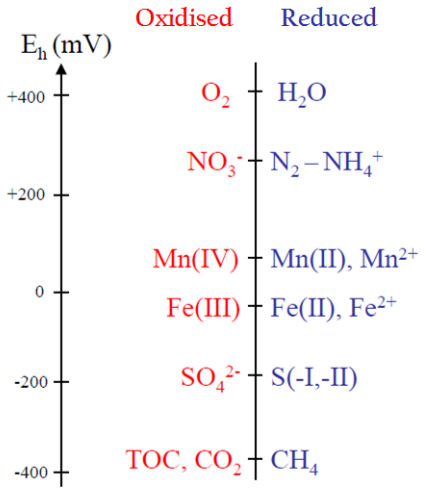

Figure 7-23. Redox ladder: electron acceptors and donors.

Aquifers with abundant electron donors tend to rapidly consume oxygen and progress quickly through the redox sequence, making water increasingly reduced. Accordingly, organic matter is the most common electron donor in groundwater. The rate of progression down the redox ladder depends on many factors including the aquifer material composition, sediment size and groundwater temperature (Rissmann, 2011).

Prevalence of non-oxidised conditions, specifically 'redox conflict' in the LMC groundwater regime greatly reduces its sensitivity to pollution by nitrate from agricultural activities. Abundant CO_2 and high pCO_2 reflect strong reducing conditions in the LMC groundwater system. If an energetically more favourable electron acceptor such as $NO3_3^-$ is introduced to such water, bacteria in the system will quickly switch to using that compound to obtain the energy it needs to decompose the available organic matter. In the process, $NO3_3^-$ will be reduced to nitrogen gas (N_2) or gaseous nitrous oxides (NO_x). Both products are poorly soluble in water and tend to float up the groundwater system as bubbles that ultimately escapes the groundwater system to the atmosphere, resulting in a net loss of nitrogen from the groundwater. This process is known as denitrification. It effectively removes nitrate from groundwater, lessening the possibility of its accumulation. Denitrification requires anoxic conditions in the groundwater marked with DO below 2 mg/L. Reduced water is normally associated with relatively high

concentrations of Fe, Mn, and NH_4^+. Oxidised groundwater conditions in New Zealand are typically characterised by nitrate concentrations greater than 1 mg/L $NO_3^- - N$, the equivalent to 4.43 mg/L NO_3^- (Daughney & Reeves, 2005).

Nitrate concentrations in groundwater in the LMC are generally low (Figure 7-24), indicating reduced groundwater conditions according to the measure suggested by Daughney and Reeves (2005) and is well below the short-term maximum allowable value (MAV) of 50 mg/L NO_3 (11.3 mg/L NO_3-N) set by the Ministry of Health (2005) in the Drinking water standards for New Zealand (DWSNZ). The nitrate MAV is intended to safeguard against methaemoglobinaemia in foetus and infants (the blue baby syndrome).

Nitrate concentrations exceed MAV only in the Levin Anticline-Koputaroa Syncline area east of Levin (Figure 7-24). The area's geology is not much different than the rest of the LMC. The area is not lacking in terms of organic material in the aquifer material (Figure 7-22). Local structure affecting Last Interglacial strata may be responsible for the noticed elevated nitrate concentrations through creating low velocity groundwater flow conditions that limit dilution of nitrate contamination from local land use activities. In addition, there are a couple of outlier high nitrate concentrations that are believed to be related to anthropogenic activities in the immediate vicinity of the affected wells, one in Cheltenham and the other in Foxton.

Nitrate concentrations in the LMC do not exceed the guidelines set by the Australian and New Zealand Environment and Conservation Council, which specify a nitrate trigger value (TV) of 400 mg/L of NO_3 as a measure for fitness of water for livestock consumption (ANZECC & ARMCANZ, 2000). The same guidelines set maximum recommended average for irrigation water of 22 mg/L of NO_3 over periods of up to 100 years (long-term) and 110-550 mg/L of NO_3 over periods of up to 20 years (short-term) to minimise nitrogen leaching into aquifers and surface water bodies.

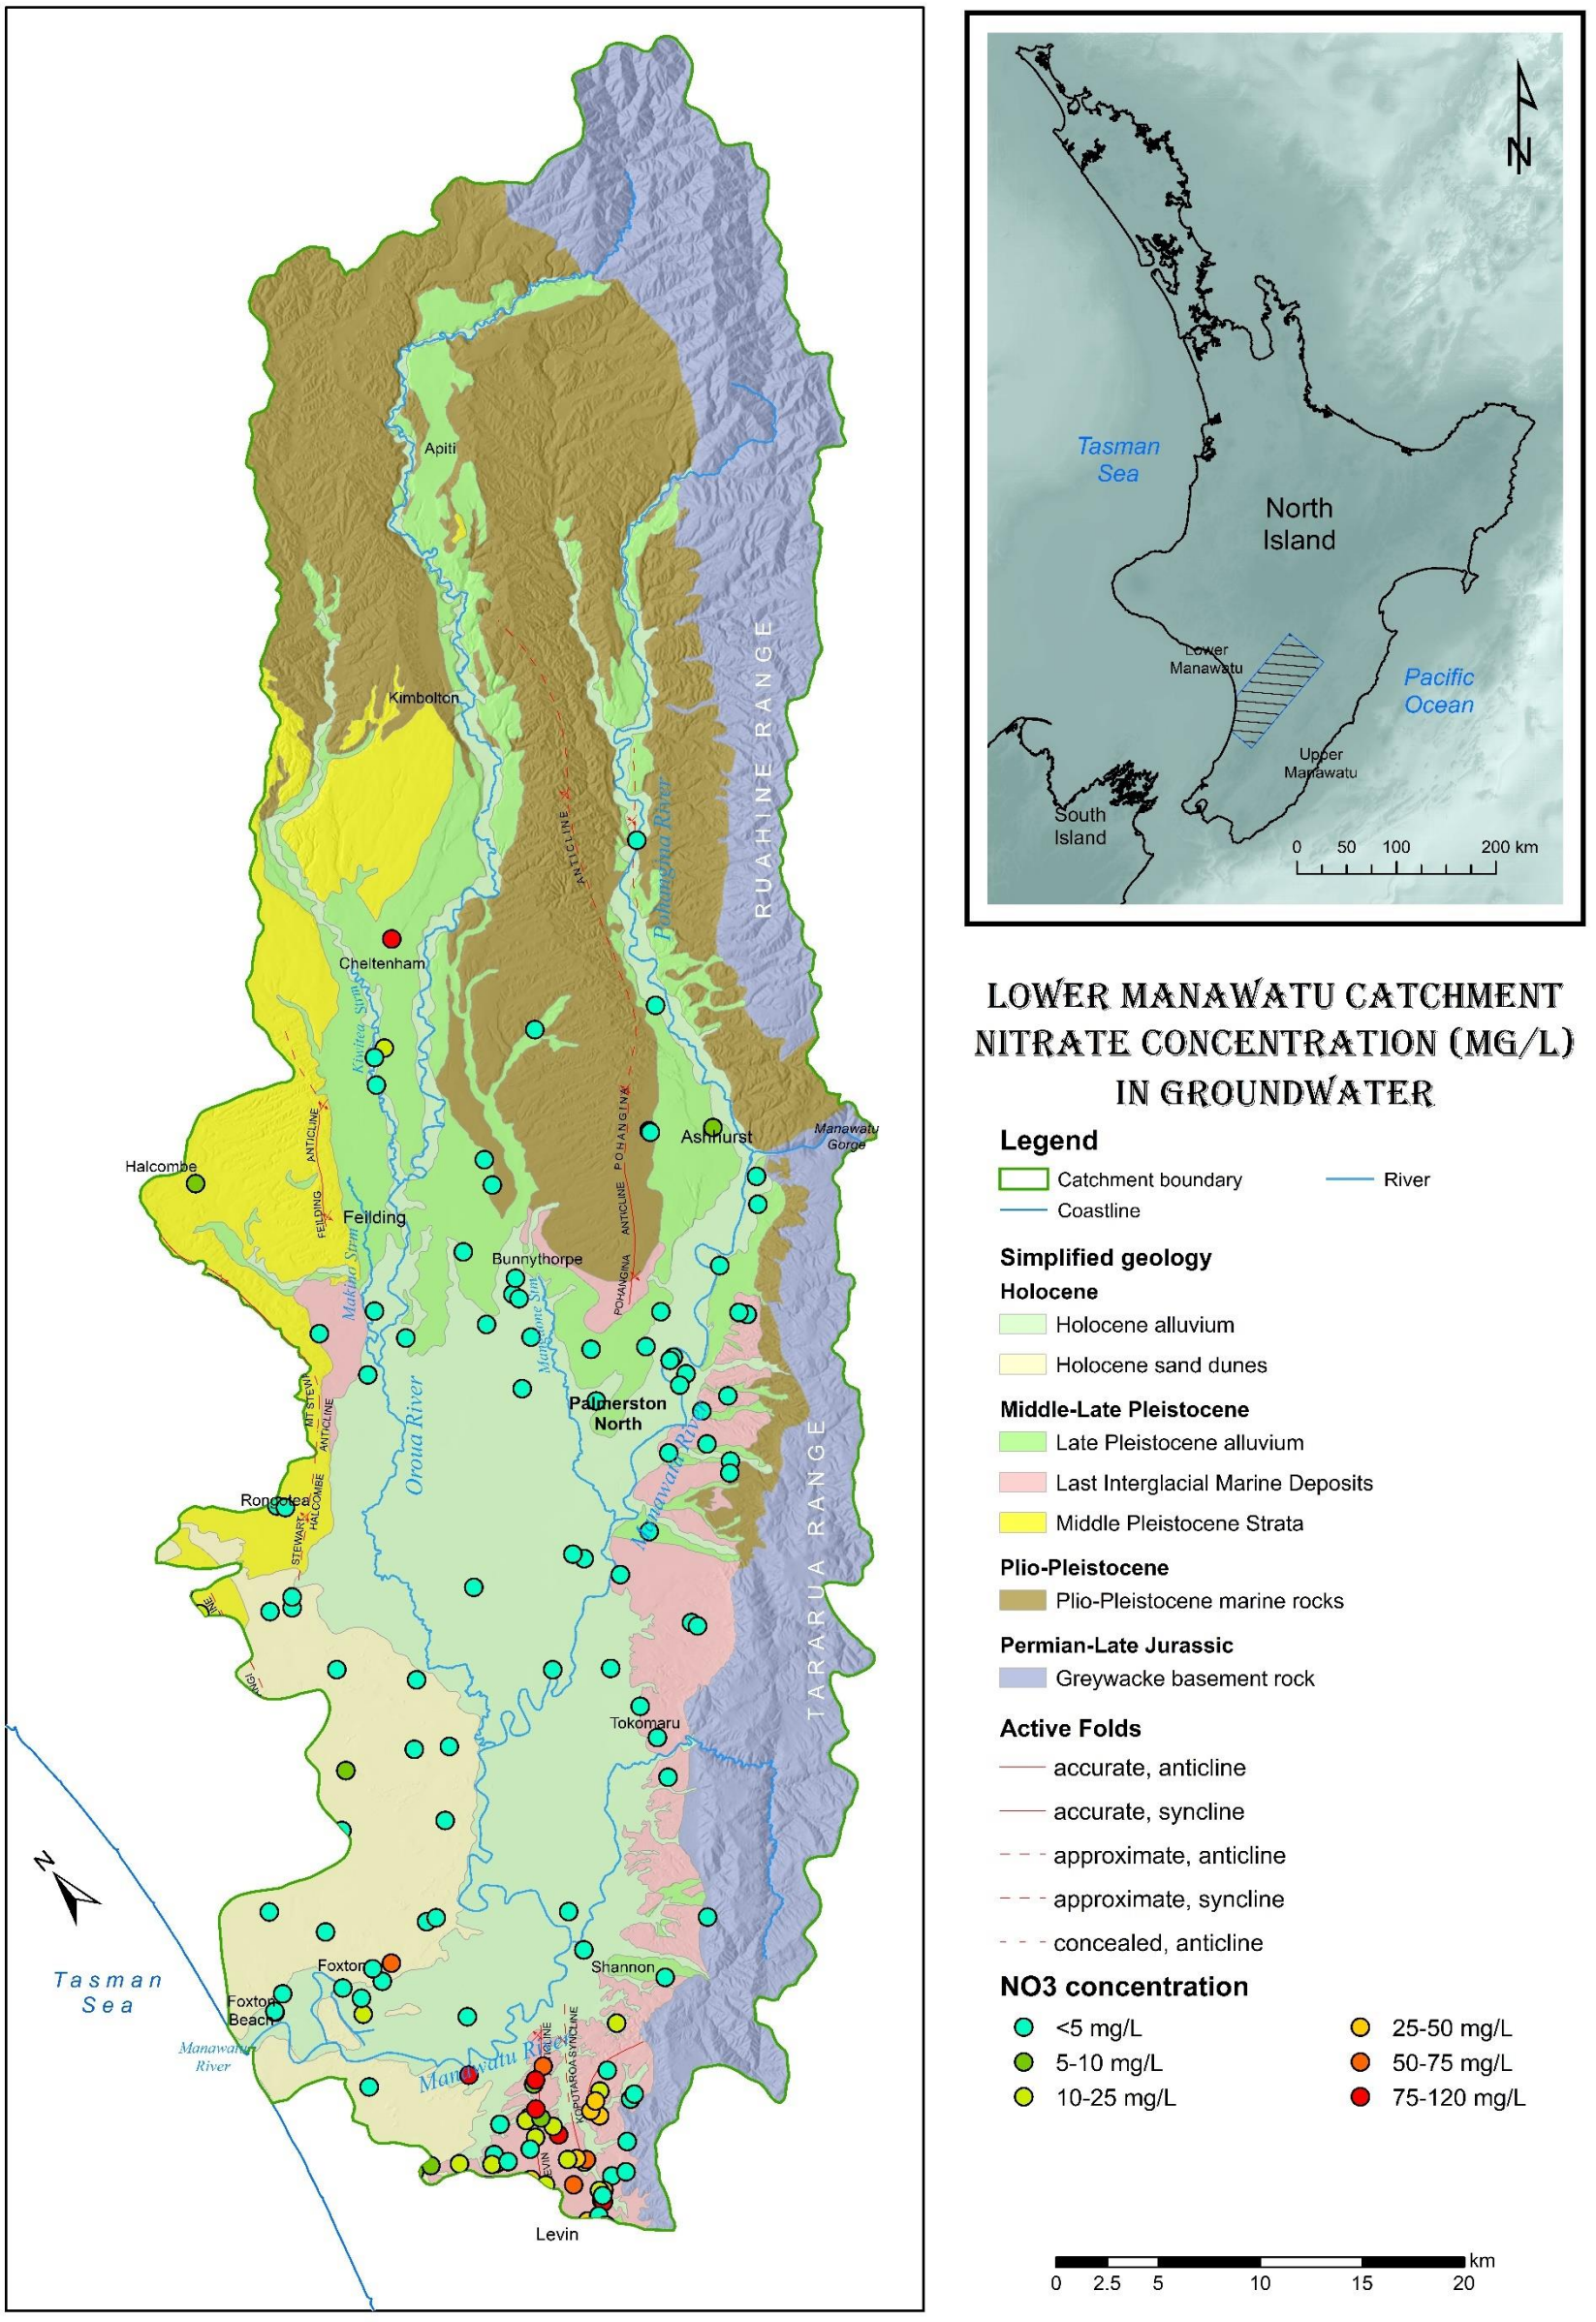

Figure 7-24. Nitrate concentration in mg/L NO_3^- in the LMC.

7.11 Groundwater quality variability with depth

Groundwater quality evolves along flow paths, which takes place in three-dimensions. Hence, the study of groundwater quality variance with depth can reveal important information about the subsurface flow system.

On a catchment-scale, there seems to be little relationship between sampled depth and salinity (Figure 7-25 and Figure 7-26). The groundwater quality-depth plots suggest that fresh and saline water can be found at any depth, shallow and deep. However, it seems more likely to encounter fresher water at greater depths, especially below 200 m below sea level. Any groundwater salinity-depth relationship may be indiscernible on the regional-scale because of the common areal change in groundwater salinity. Therefore, local-scale scrutiny is needed to adequately check the groundwater quality-depth relationship.

There are no multi-level groundwater quality monitoring wells in the LMC. To compensate for that, eight clusters of wells screened at different depths have been selected to check on the relationship between hydrochemistry and depth using representative samples. Table D-4 in Appendix D lists the wells in these clusters and Figure 7-27 shows their locations.

Figure 7-28 (p 229-232) shows changes in the main groundwater parameters with sampling depth expressed as the elevation of the bottom levels of sampled wells at the selected eight sites. Overall, groundwater quality-depth plots presented in Figure 7-28 suggest that salinity and concentrations of major constituents generally decrease with depth. This observation is consistent with the findings of previous investigators (e.g. Lieffering, 1990; Russell, 1989; Schumacher, 1999). In contrast, pH tends to increase with depth.

The groundwater-quality-depth plots presented in Figure 7-28 imply that groundwater quality in the LMC is sensitive to pH, which is dependent on HCO_3^-

concentration. Higher water acidity at shallow depths result in greater dissolution of minerals and, hence, higher salinity. Alkaline groundwater at depth is fresher and is saturated with respect to carbonate minerals such as calcite, aragonite and dolomite as indicated by their saturation indices (SIC, SIA and SID, respectively).

7.12 Groundwater suitability for various uses

To assess groundwater suitability for human consumption, groundwater quality parameters in representative samples have been compared to the Drinking water standards for New Zealand (DWSNZ 2005). To assess suitability of the water for irrigation and livestock supply, representative samples were tested against the Australian and New Zealand Environment and Conservation Council, which specify a nitrate trigger values (ANZECC 2000). Daughney *et al.* (2009) summarised the most important water quality guideline values in the DWSNZ 2005 and ANZECC 2000 (Table 7-4). Table D-5 in Appendix D summarises exceedances of DWSNZ 2005 MAVs and GVs.

Acidity higher than MAV and GV is common place in groundwater in the LMC and the oxidised conditions generally do not exist. As a result, high metal content is common place as exemplified by 160 exceedances of Mn GV, including 96 exceedances of Mn MAV, and 149 exceedances of Fe GV. The redox conflict status of groundwater is exemplified by samples showing elevated NO_3 together with high NH_4, Fe and Mn. The pattern of groundwater quality exceedance of DWSNZ 2005 does not display any clear relationship with location, depth, geology, connectedness with surface water or land use.

Table 7-4. important water quality guideline values in the DWSNZ and ANZECC 2000 (after Daughney *et al.*, 2009)

Parameter	Units	DWSNZ 2005		ANZECC 2000	
		MAV [53]	GV [54]	Irrigation TV [55]	Livestock TV [55]
EC	µS/cm	-	-	600-12,800 [56]	-
TDS	mg/L	-	1,000	-	2,000-5,000
pH	pH units	-	7.0-8.5	6-8.5	-
Turbidity	NTU	-	2.5	-	-
Ca	mg/L	-	see Hardness	-	1,000
Mg	mg/L	-	see Hardness	-	-
Hardness	mg/L $CaCO_3$	-	200	>60 and <350 [57]	-
Na	mg/L	-	200	<115 to >460 [58]	-
Cl	mg/L	-	250	<175 to >700 [58]	-
Fe	mg/L	-	0.2	10	not sufficiently toxic
Mn	mg/L	0.4	0.04	10	not sufficiently toxic
B	mg/L	1.4	-	<0.5-15	5

F	mg/L	1.5 [59]	-	2	2
NH_4	mg/L	-		-	-
NO_2	mg/L	3 [60]		22 or 110-550 [61]	30
NO_3	mg/L	50 [62]			400
$PO_4 - P$	mg/L	-		0.05 or 0.8-12 [63]	-
SAR					
Extremely sensitive	-	-	-	<2-8	-
sensitive	-	-	-	<8-18	-
medium	-	-	-	<18-46	-
high	-	-	-	<46-102	-

Some groundwater in the LMC exceed ANZECC 2000 irrigation and livestock trigger values, but groundwater in the LMC is generally suitable for agricultural activities.

[53] Maximum Allowable Value (MAV) for parameters of significance to human health.
[54] Guideline Value (GV) for parameters of aesthetic significance.
[55] Trigger Values (TVs) are for short term exposure, and a range of higher values may be tolerated depending on the type of crop/livestock.
[56] General guide for EC of irrigation water at the threshold level for a range of plants and soil types: for sensitive crops in poorly draining soil, EC should be less than 600 µS/cm, whereas more tolerant crop types in well-drained soil may withstand EC above 12,000 µS/cm.
[57] Hardness <60 mg/L CaCO3 has an increased corrosion potential, >350 mg/L CaCO3 has an increased fouling potential. DWSNZ 2005 does not specify a health-related MAV for hardness.
[58] Concentration causing foliar injury depending on crops sensitivity: <115 mg/L Na and <175 mg/L Cl for sensitive crops, up to >460 mg/L Na and >700 mg/L Cl for tolerant crops. High levels of chloride in irrigation water trigger the risk of increasing cadmium concentrations in crops: <350 mg/L risk is low.
[59] For oral health reasons, the Ministry of Health recommends that the fluoride content for drinking-water in New Zealand be in the range of 0.7-1.0 mg/l; this is not a MAV.
[60] A GV of 1.5 mg/L is specified as an odour threshold, and in addition, NH4 concentration should be less than 0.3 mg/L in cases where treatment for use as drinking water requires addition of chlorine.
[61] Now short-term only. The short-term exposure MAVs for nitrate and nitrite have been established to protect against methaemoglobinaemia in infants.
[62] TVs are set for minimisation of nitrogen leaching into aquifers and surface water bodies: long-term TV (maximum recommended average over periods of up to 100 years) is 22 mg/L for NO3 as a generic guide, whereas short-term TV (maximum recommended average over periods of up to 20 years) is between 110 and 550 mg/L and is site-specific and considers the crop being grown.
[63] The long-term TV (maximum recommended average over periods of up to 100 years) is 0.05 mg/L for PO4-P is set to minimise algal growth in irrigation water. The short-term TV (maximum recommended average over periods of up to 20 years) is 0.8 to 12 mg/L PO4-P to minimise phosphorus leaching to aquifers and surface waters, and is site-specific depending on fertiliser input and the fraction of phosphorus taken up by plants and soils.

The Wilcox plot presented in Figure 7-29 suggests that groundwater salinity hazard is acceptable (EC<1000 μS/cm) and only five samples record higher than S1 level sodium hazard, rendering LMC groundwater generally suitable for irrigation.

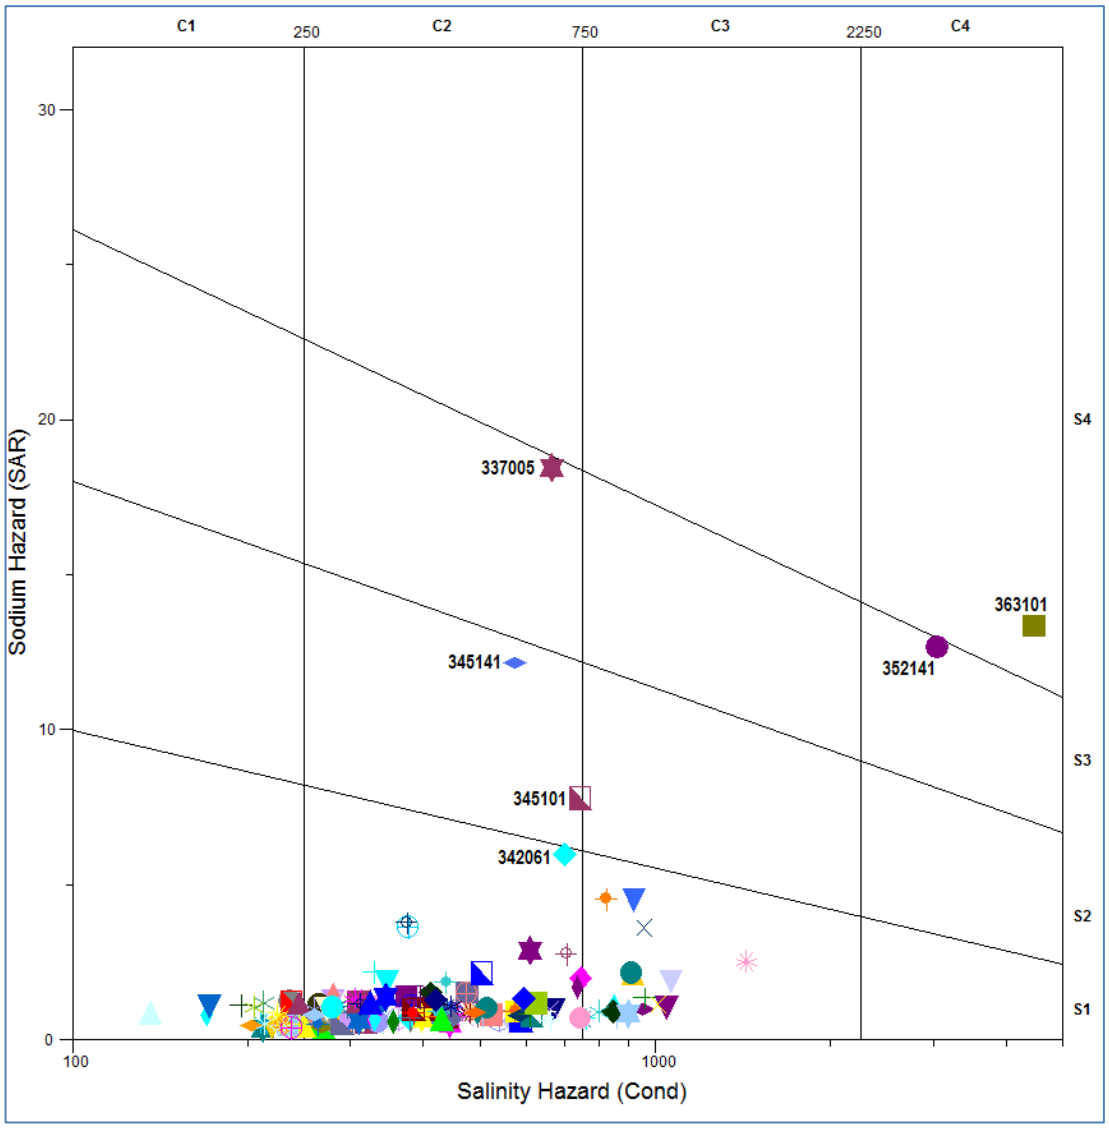

Figure 7-29.Wilcox plot for representative groundwater samples from the LMC.

7.13 Summary

Data collected from the start of groundwater quality monitoring in the LMC until the end of 2007 are a useful resource for hydrochemical analysis. They include 1,584 records relating to 631 wells in and around the LMC. Noticeably, there are no data from areas topographically higher than 160 masl.

Representative samples for 268 wells have been used in the analysis presented in this thesis. They satisfactorily cover the LMC below 160 masl and represent various depths. However, available groundwater quality data cannot be used to determine flow paths, recharge and discharge zones, or the relationship between groundwater and surface water features in the area.

Like previous investigations, this research has not detected seasonal variability or long-term trends in groundwater quality records in the LMC. In terms of groundwater quality variability with depth, this research confirms the findings of previous investigators that groundwater salinity improves with depth, probably due to the prevalence of reduced conditions and higher pH that result in lower solubility of alkaline minerals.

Groundwater quality in the LMC is dominated by fresh groundwater recharge water facies ($Ca-HCO_3$ and $Ca-Mg-HCO_3$ water types). However, there seems to be areas of ion exchange that result in relatively elevated Na^+ concentrations along the Tararua Range foothills and in the Levin Anticline and Poroutawhao Basement High areas, resulting in the existence of $Na-HCO_3$ to $Na-Cl$ water facies. The Levin Anticline area is also characterised by high nitrate concentrations that are believed to relate to local sources and low groundwater flow velocities. Away from the Levin Anticline area, human impacts on groundwater quality are not evident. This is believed to be related to the lack of oxidised groundwater conditions due to the presence of organic matter in the stratigraphy, mainly reported in drillers' well logs as peat.

Overall, groundwater in the LMC is suitable for human consumption, irrigation and livestock, with exceptions relating principally to natural conditions across the general LMC area and anthropogenic influences in the Levin Anticline area. Natural limitations mainly include elevated Mn and Fe, and low pH (acidity). Elevated nitrate concentrations in the Levin Anticline area pose a health risk to unborn babies and infants. There is no indication of seawater invasion into the aquifer in the coastal area.

Chapter 8 LMC groundwater flow model

8.1 Introduction

Mathematical modelling has revolutionised earth sciences, particularly by enabling us to understand physical processes that occur over prolonged times (Ellis *et al.*, 2008). Hydrogeological processes may look short-lived in comparison to other geological phenomena, but mathematical modelling is still very useful when it comes to understanding groundwater flow dynamics and aspects that control them. Mathematical modelling is also a powerful tool for exploring matters that cannot be directly seen like groundwater and helps communicating our conceptualisations on them. In this thesis, mathematical modelling is intended to provide an overarching analytical framework for multidisciplinary data synthesis and hydrogeological analysis.

8.2 Objectives and strategy

The foremost step in any modelling exercise is to set up its objective (e.g. Anderson *et al.*, 2015; Barnett *et al.*, 2012; PDP, 2002; Reilly & Harbaugh, 2004; Wels *et al.*, 2012; Younger, 2007). The main objective of the groundwater flow modelling work completed in this research is to validate the characteristics of the LMC groundwater flow system presented in the previous chapters and explore the fundamental constituents and processes that affect the area's hydrogeology. The numerical modelling component of this research is also intended to:

(1) help communicate the findings of the research

(2) provide a useful tool for stakeholders to enable assessment of land and water use management options and help them with decision making

(3) provide basis for further work.

In conformity with the principle of parsimony, also known as the Ockham's razor[64], '*Entia non sunt multiplicanda praeter necessitatem*'[65], both the conceptual and numerical models developed for the LMC groundwater system have been kept as simple as possible and as complex as needed. In dealing with various components of the models, the level of complexity has been stepped up only when that has been unavoidable and only to the degree that is necessary.

8.3 Hydrolithostratigraphical framework

Bona fide understanding of the groundwater system's hydrolithostratigraphical setting and characteristics is a prerequisite to reliable hydrogeological conceptualisation. There have been a few attempts to construct stratigraphical models for parts of the LMC, some are published (e.g. Martley, 2001; Schumacher, 1999) and some are found in Horizons Regional Council's old database, unpublished drawings and internal reports. Previous work mainly focused on interpolation between gravelly stratigraphical horizons reported in drillers' well logs, attempting to define aquifers. In this research, stratigraphical interpolation is not intended to define aquifers, but to depict a hydrolithostratigraphical framework that can be used in conceptual and numerical hydrogeological modelling.

8.3.1 Data sources, limitations and uncertainty

GNS Science QMAP sheets are the most obvious and reliable source of stratigraphical information. Drillers' well logs in Horizons database can help understand the subsurface geology. Published work like the seismic data interpretation by Melhuish *et al.* (1996) can also aid the process.

Different types of data from various sources have been synthesised to create the stratigraphical model presented below. The data used included the DEM and the geological map described in sections 3.3.1 and 3.3.2, respectively. The scale and accuracy of the used topographical and geological data are not suited for local-

[64] Also spelt Occam's razor.
[65] Roughly meaning: more things should not be used than are necessary.

scale interpolation, but they are considered sufficient for the purposes of this catchment-scale groundwater study.

Drillers' well logs have been heavily utilised in this research. They were obtained in digital format from Horizons Regional Council. This dataset is a computerised version of the manually recorded lithological descriptions by drillers. Drillers' well logs are very useful but they are subject to limitations that introduce various levels of uncertainty that must be acknowledged and considered when utilising such data in geological and hydrogeological investigations. The LMC area is not evenly covered by well log data, and not all well logs have been used in the construction of the stratigraphical model presented in this thesis for practicality reasons and data quality considerations. Figure 8-1 shows the locations of wells with drillers' description in the LMC, real and imaginary wells and cross-sections (Section 8.3.2, p 246) used in stratigraphical modelling in this research. Drillers' well logs are considered the most imprecise and uncertain data used in this research. These data are subject to the following five main areas of limitation and error:

1. Well position and level

Wells with drillers' lithological descriptions can have estimated or precise positions. Well position estimates have traditionally been obtained from topographical maps, aerial photographs, and starting from 2006 using handheld global positioning system (HGPS) devices. Wells precisely positioned have been traditionally surveyed with theodolite, but recently using differentially corrected global positioning system (DGPS) technology. Surveyed wells have accurate easting, northing and elevation data. Elevations of non-surveyed wells have been traditionally estimated from topographical maps and more recently using DEMs. Such estimates are more uncertain than values obtained from surveying. Some of the wells that have drillers' logs have been surveyed for elevation using optical levelling techniques, but their locations are estimated. It goes without saying that if the location data are inexact, elevation data will be doubtful at best.

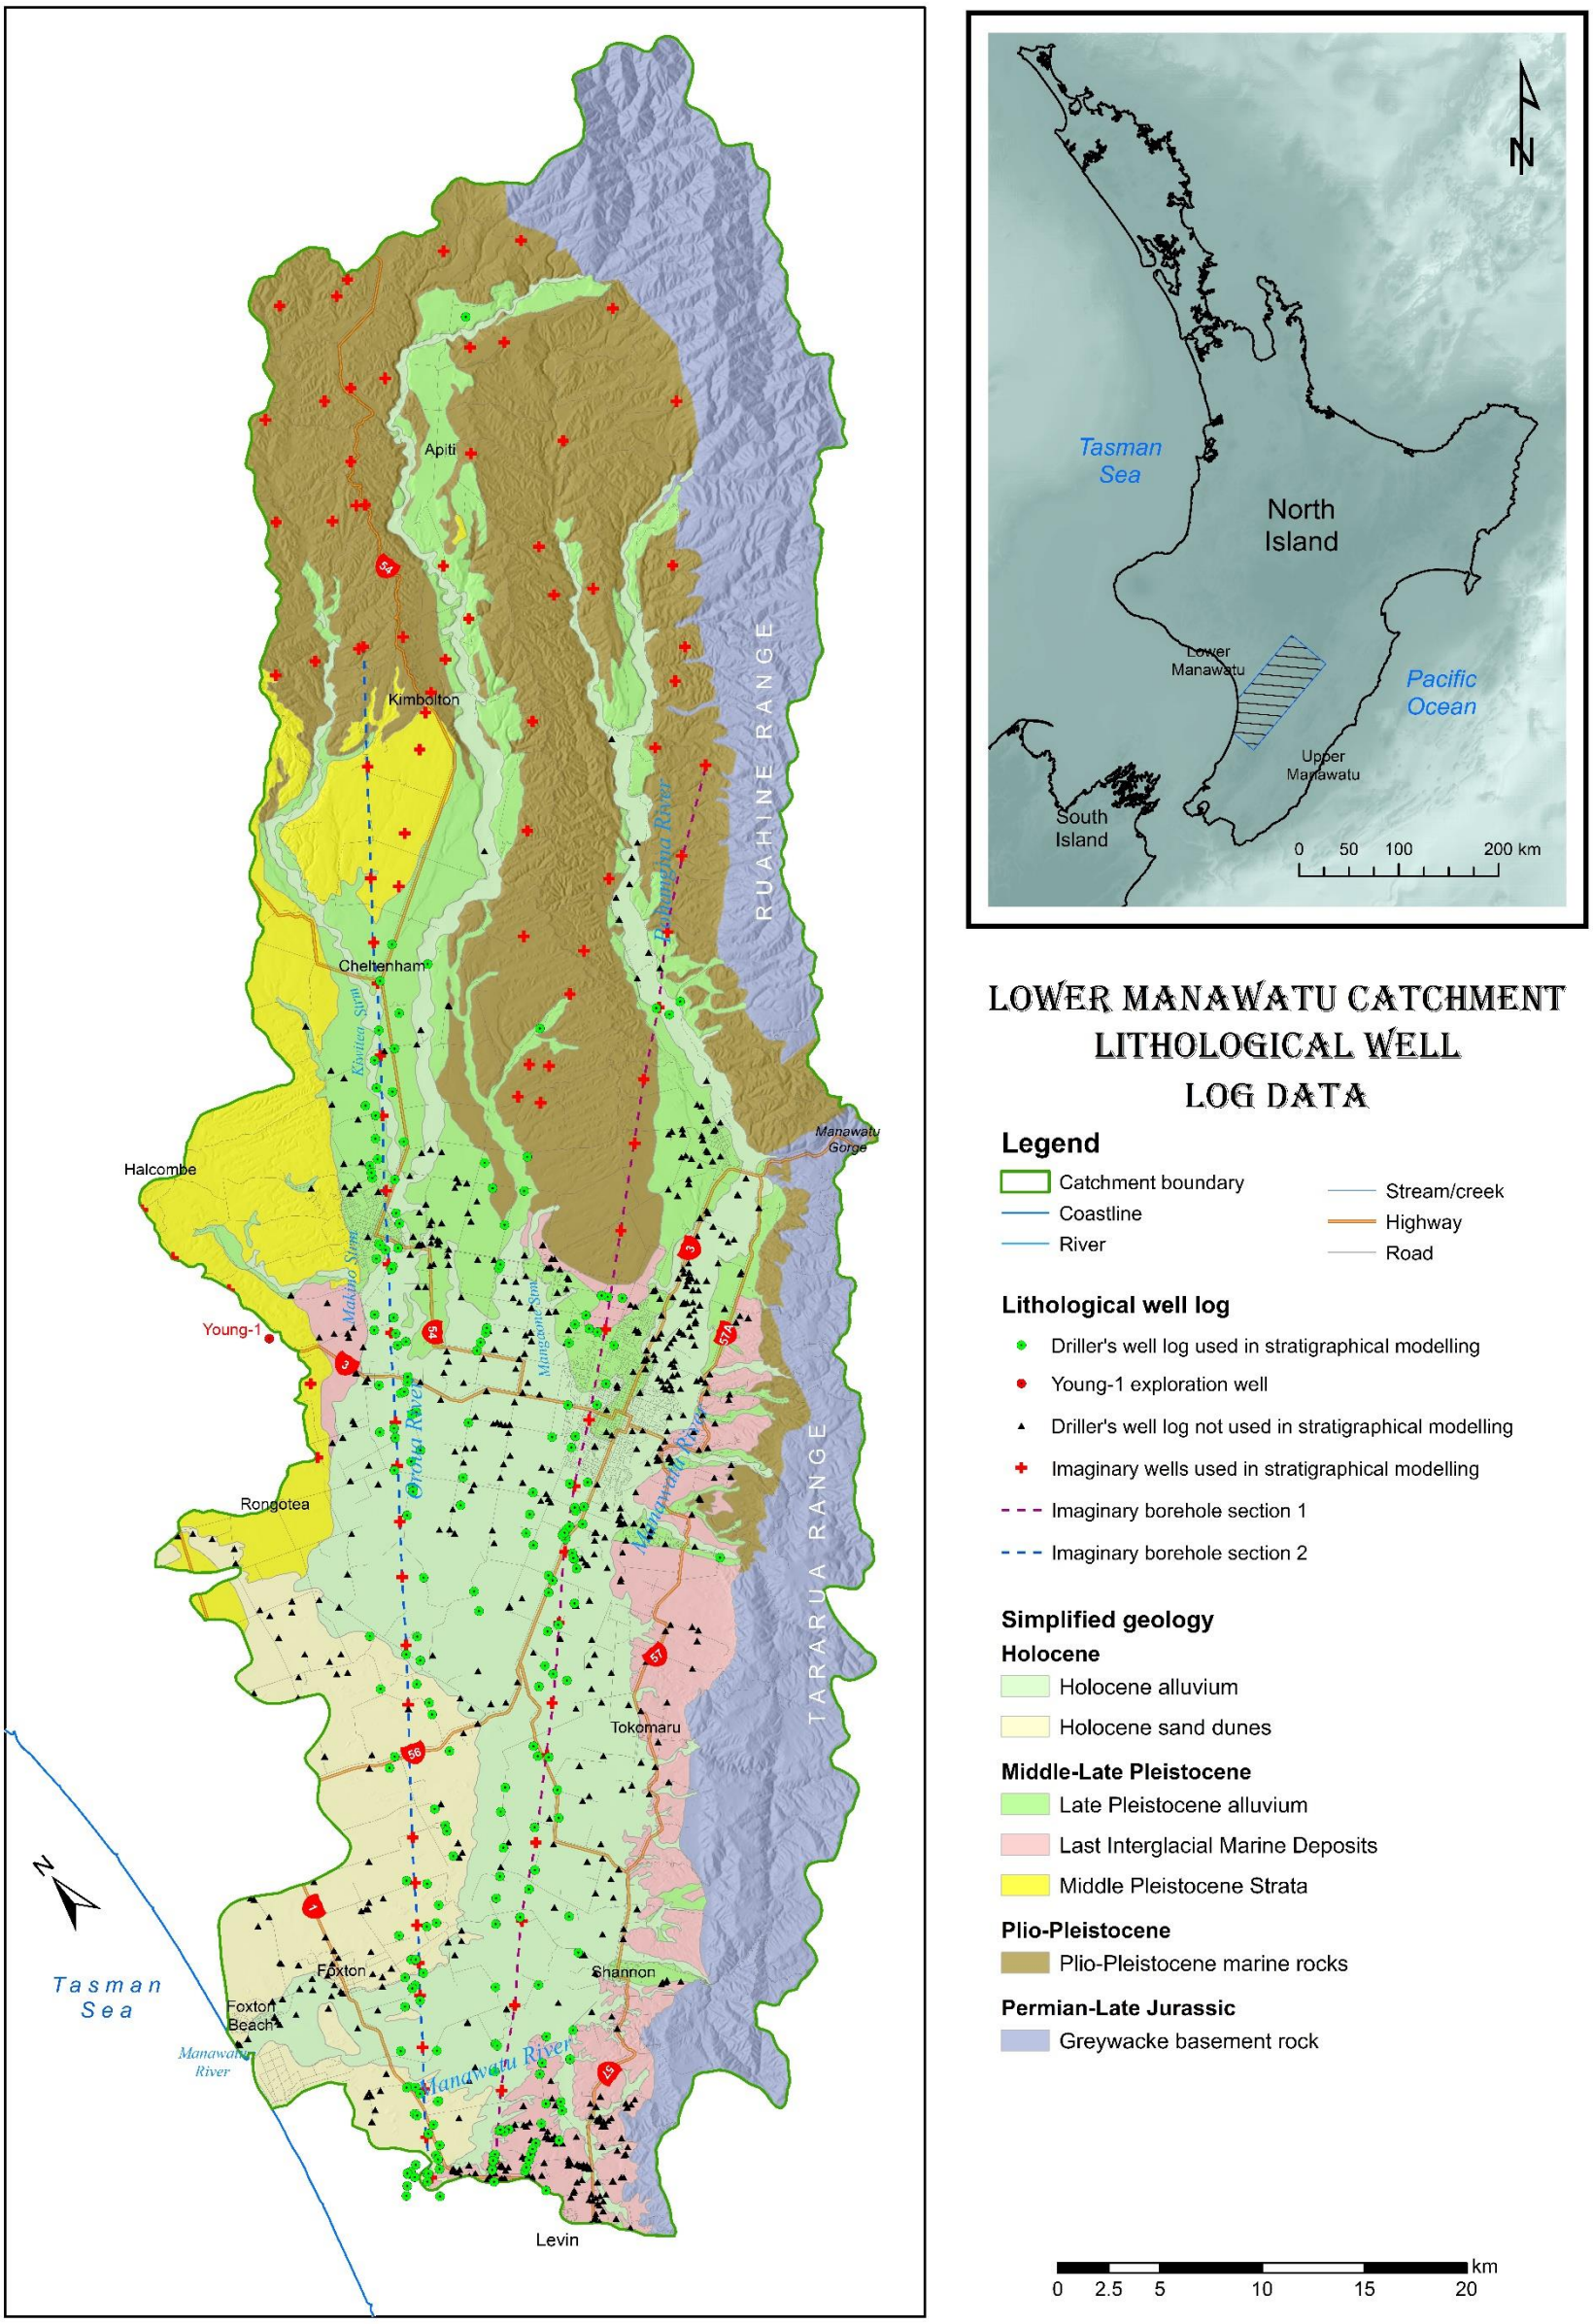

Figure 8-1. Location map showing wells with drillers' description in the LMC, real and imaginary wells and cross-sections used in the construction of the stratigraphical model presented in Section 8.3.3.

2. Sample depth representativeness

All available drillers' lithological records have been obtained from ordinary water production wells rather than exploration boreholes. These wells have been drilled with a variety of methods and lithological sampling was not critical or a priority in the process. Hence, there is a considerable degree of uncertainty associated with lithological sample depths despite some drillers' records suggesting millimetre precision.

3. Lithological description

Available lithological data from wells in the LMC come from drillers' descriptions, not from geologists' logging. Noticeably, the level of detail and used terminology in available lithological records are highly variable. They clearly vary from one drilling company to another, but also amongst operators in the same company. Even geologists may have inconsistencies in describing material from drilling returns.

Schumacher (1999) developed an approach to relate drillers' descriptions to usable lithological classes (Table 8-1). This classification is particularly useful when combined with the general characterisation of lithological units by Begg *et al.* (2005) presented in Table 8-2.

4. Level of detail and description usefulness

Some drillers' well log records are lacking on detail, whereas some provide too much information that is not all relevant. For example, a record in a well log may simply provide a colour (e.g. grey) or a relative descriptor (e.g. better than above) to characterise a lithological facies in the well log. Some descriptions are also impossible to be obtained from well logs, e.g. clay lens. In addition, the only mention of fossils in drillers' well logs is through the occasional recording of shells or pieces of temper, without further clarification. There is no mention in all reviewed well logs to tephra, which would have been very helpful as a stratigraphical marker in well log interpolation and correlation.

Table 8–1. Commonly used drillers' descriptions of rock and soil units in well logs and their most likely lithological interpretation (adapted after Schumacher, 1999).

* Unnamed in Begg *et al.* (2005)

5. Typographical errors and terminology inconsistency

Typographical errors have been noticed in both original drillers' paper records and Horizons digital groundwater database. Most of the paper record errors transpire into the digital record. In addition, there is noticeable terminology inconsistency in well logs. For example, gravel is variably referred to as conglomerate, metal, shingle and, of course, gravel. Correcting typographical errors and terminology standardisation will be required if drillers' well log records are to be digitally queried, which has not been the case in this research.

8.3.2 Stratigraphical modelling methodology

The LMC hydrolithostratigraphical system is conceptualised as a sequence of predominantly marine Plio-Pleistocene rocks onlapped by alternating marine and terrestrial Middle-Late Pleistocene poorly consolidated strata, with Holocene alluvium filling the valleys and covering the floodplains and Holocene dune sands mantling the coastal area (Section 6.3). To enable digital synthesis and representation of the stratigraphical system, geological information from literature and the QMAP has been used to classify the LMC's stratigraphy into the units shown in Table 8-3. Each unit has been designated a hydrogeological unit code (HGUCode) to uniquely identify it and a Horizon ID to denote its top (contact with overlying unit, where applicable). Horizon IDs are assigned to units in order of deposition, from older to younger. HGU coding and Horizon ID numbering can include gaps, e.g. there are no HGUCode 7 and Horizon ID 9 in Table 8-3. Initial hydraulic conductivity values and ranges have been determined based on the perceived lithology of various units from QMAP data (Table 3-1), Begg *et al.* (2005) lithological descriptions (Table 8-2), drillers' lithological descriptions, and textbook values (Table 6-1, Table 6-2, Figure 6-3 and Table 8-1).

Interpretation of well logs entail identification of stratigraphical units, marking their upper contacts and assigning Horizon IDs to the identified contacts. Correlation between well logs can then be made through linking the contacts identified at wells. Stratigraphical Horizon IDs can also be assigned to stratigraphical outcrops, enabling correlating subsurface units to outcrops.

Table 8-3. LMC stratigraphical model units.

HGUCode	Horizon ID	Symbol colour	Code	Description	General lithology	Initial K value (m/d)	Expected K range (m/d)
1	15		Q1s	Holocene sands	Sand	0.15	0.1–1
2	14		Q1a	Holocene alluvium	Gravel	100.00	1–1,000
4	12		Q4–2a	Last Glacial alluvium	Gravel, sand	10.00	0.1–50
6	10		Q5b	Last Interglacial beach deposits	Sand, silt, minor gravel	20.00	1–100

15	1		Bs	Basement rock	Indurated rock	—	—

Initially, lithostratigraphical correlation and modelling have been attempted following the workflow shown in Figure 8-2. However, direct lithostratigraphical correlation proved to be prohibitively difficult and incapable of providing a complete picture of the area's lithostratigraphy. Subsequently, it has been decided to construct the needed 3D stratigraphical model based on modelled cross-sections, imaginary wells and selected interpreted drillers' well logs. Figure 8-1 shows the two strategically aligned cross-sections lines used in the process and various types of well logs used in the process. All imaginary wells have been extended from the land surface to 350 m below mean sea level and all stratigraphical units thought to exist in each imaginary well site have been marked from the ground level to the bottom of the imaginary well. Thereafter, stratigraphical units at the imaginary wells have been correlated and extrapolated between the imaginary wells to create the cross-sections presented in Figure 8-3.

Stratigraphical analysis and correlation have been an iterative process. Imaginary wells have been placed in areas with relatively abundant drillers' well log records and/or surficial contacts between stratigraphical units. Drillers' well log records around each imaginary well have been examined to estimate stratigraphical contacts at each actual well, comparing the initial stratigraphical interpretation to nearby wells and outcrops, then assign stratigraphical Horizon ID to unit contacts on the imaginary wells and, where feasible, on the real wells. Key information that helped in lithostratigraphical interpolation included grain-size descriptors (e.g. gravel, sand, silt) and the presence of peat/organic matter. Peat and organic matter are repeatedly reported in well logs (Figure 7-22) and have been noticed to be associated in the LMC mainly with interglacial shallow/marginal marine deposits (e.g. Q5b and Q7b). Interpretation of drillers' descriptions also depended on the location of the well. For example, sand reported in a driller's log as the top most layer in Q1a outcrop area is considered part of the Q1a alluvial unit. Thickness has been considered in the interpolation so that thin layers have been ignored and considered part of the larger surrounding sequence. For example, gravelly units only few centimetres thick that fall in a few metres thick sequence of sands and peat have been commonly ignored in the stratigraphical interpretation. Change in

stratigraphical facies has been allowed for in the interpretation. For example, the Q5b unit become sandier between Opiki and the coastline.

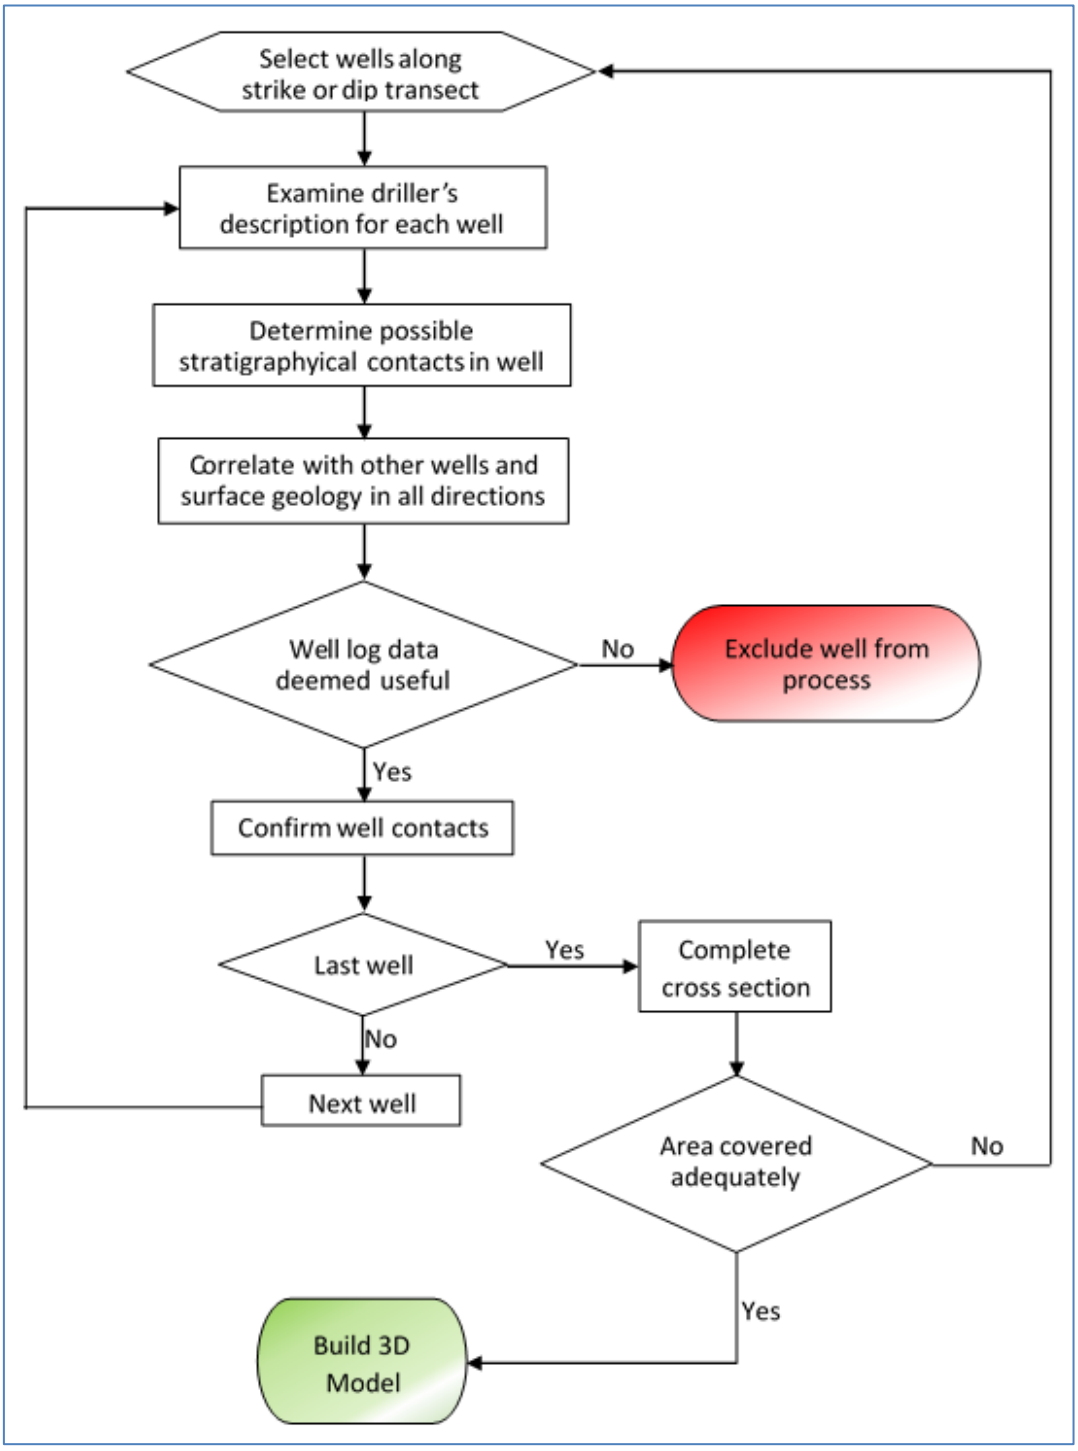

Figure 8-2: Flow chart illustrating attempted and abandoned stratigraphical model construction methodology.

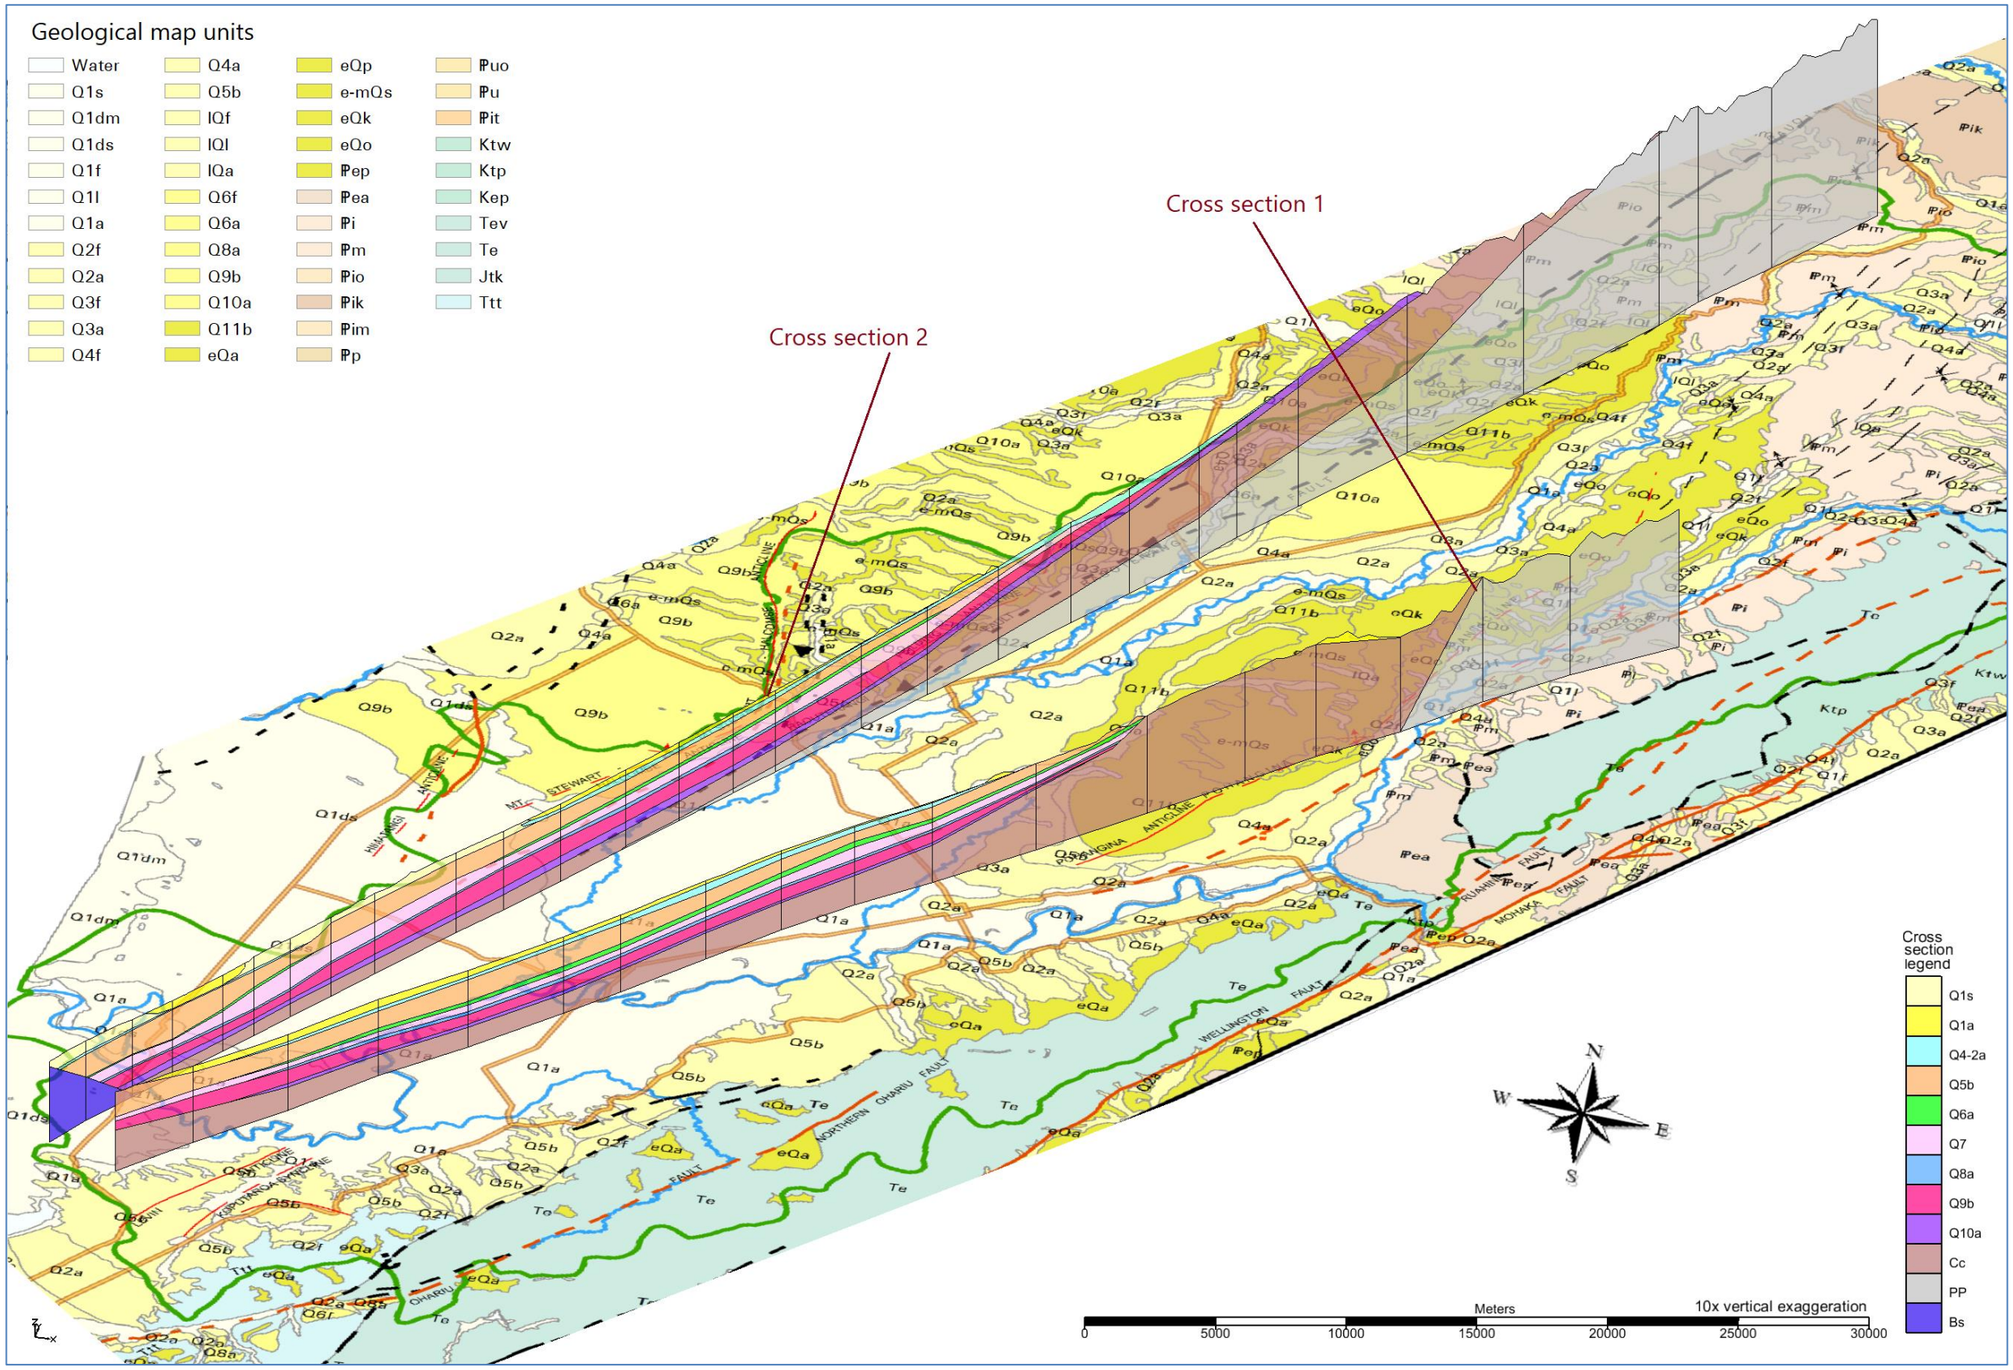

Figure 8-3. Stratigraphical cross-sections extrapolated between imaginary wells to help with 3D stratigraphical modelling.

Basement greywacke rock (Bs) has been identified in a few wells in the Poroutawhao Basement High area. This rock is easy to distinguish in well logs and is normally described by drillers as hard rock. However, all other borehole log units had to be recognised by considering the reported lithology and figuring out possible depositional environment, mainly marginal/shallow marine, aeolian terrestrial, or fluvial terrestrial to enable matching them to model layers.

As can be seen in Figure 8-1, there is a dearth of well log data in the upper part of the LMC. Therefore, imaginary wells have been placed in that area to model its stratigraphy based on published layer thickness and structure information (strike and dip). Melhuish *et al.* (1996) analysis has been particularly enlightening of the subsurface geology in this area of the LMC. Their seismic interpolation incorporated lithological data from three oil exploration wells, the Mount Stewart-Halcombe Anticline Young-1 and the Marton Anticline Stantiall-1 wells drilled in 1942 and the Santoft 1A well drilled in 1964 near the coast, west of Bulls. The Young-1 well is situated c. 5 km to the west of Feilding, less than c. 500 m to the west of the LMC boundary. All three wells reached the Torlesse greywacke basement. According to Melhuish *et al.* (1996), Nukumaruan sediments lie on basement, which is found at 1,100 m depth in the Young-1 well, the bottom of the Castlecliffian Series lies at c. 550 m depth, c. 40 m of Haweran sediments were deposited across the entire Mount Stewart area before continuing regional uplift combined with folding created the present-day topography, and the depth to basement is fairly uniform along the entire crest of the Mount Stewart-Halcombe Anticline. Melhuish *et al.* (1996) clarify that the sedimentary sequence is folded into a broad, gently asymmetric anticline whose eastern limb dips more steeply than the western limb (c. 22° and c. 6°, respectively). This information has been used to estimate the contacts of various stratigraphical units in imaginary wells in the upper parts of the LMC.

Figure 8-3 shows that the stratigraphical units listed in Table 8-3 do not cover the entire LMC stratigraphical model domain. Subsequently, the extent of spatial interpolation and extrapolation of the model's various different units had to be

identified in the modelling process (Figure 8-4). The determination of the possible spatial extent of most unit is based on surface geological information except for the antepenultimate and penultimate glacial periods deposits (Q8a and Q6a, respectively) and the basement rock unit (Bs), which do not crop out in the LMC groundwater system model area. Stratigraphical unit extents were delineated assuming that marine units cannot extend beyond the extents of the underlying units in the up-dip direction and terrestrial areas are limited to their river courses and floodplains. Structural geology and well log data have been considered in drawing the unit extent maps shown in Figure 8-4. The boundary delineating the area of occurrence of a stratigraphical unit can either be an inside or outside line. Inside boundary lines define contacts between units, e.g. Q1a and Q4-2a, whereas an outside boundary demarks an external model boundary, which does not mean that the stratigraphical unit stops at that boundary but the model ends. The watershed line between the Manawatu and Rangitikei catchments is an example of an outside boundary for some model units that extend across it, e.g. Q9b.

GMS software has been used in storing and visualising stratigraphical well log data, interpreted well logs and cross-sections, constructing the 3D stratigraphical model and incorporating it into a flow model. Figure 8-5 presents the developed LMC stratigraphical model as a block diagram and Figure 8-6 presents it as a fence diagram.

8.3.3 LMC stratigraphical model

Figure 8-3, Figure 8-5 and Figure 8-6 show that structure has a profound influence over the area's stratigraphy. The system configuration is largely determined by faults and folds like the Northern Ohariu Fault, Pohangina Anticline, Wellington Fault, Ruahine Fault, Rauoterangi Fault, Feilding Anticline, Mt Stewart-Halcombe Anticline, Himatangi Anticline, Levin Anticline, Koputaroa Syncline, and Shannon Anticline. These structures both determine the extent of the groundwater flow system and the extent of hydrolithostratigraphical units within it.

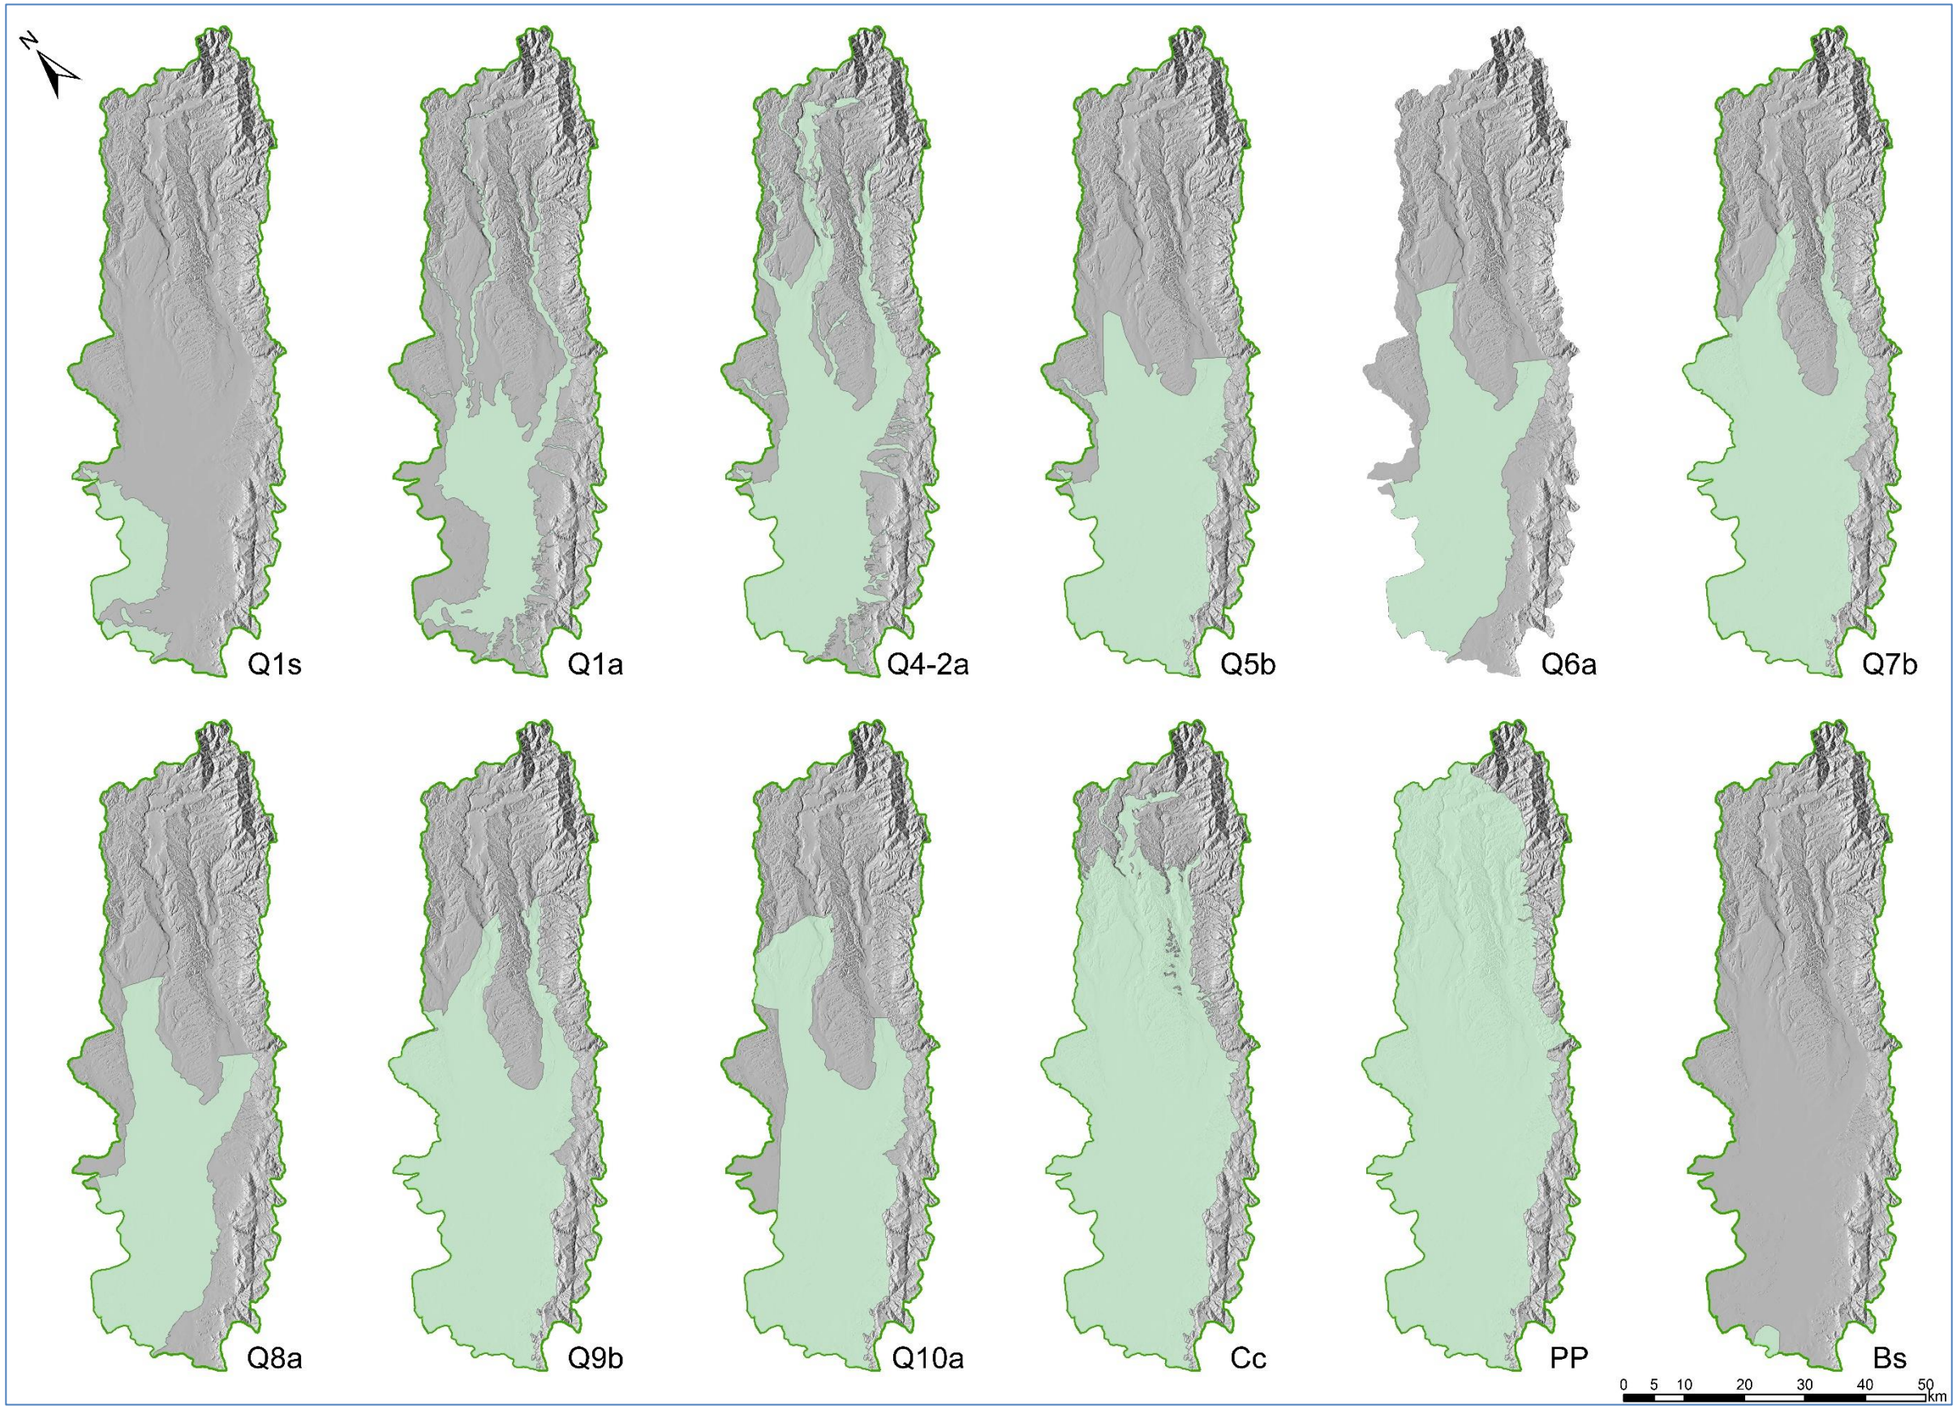

Figure 8-4. Perceived possible extent of stratigraphical units.

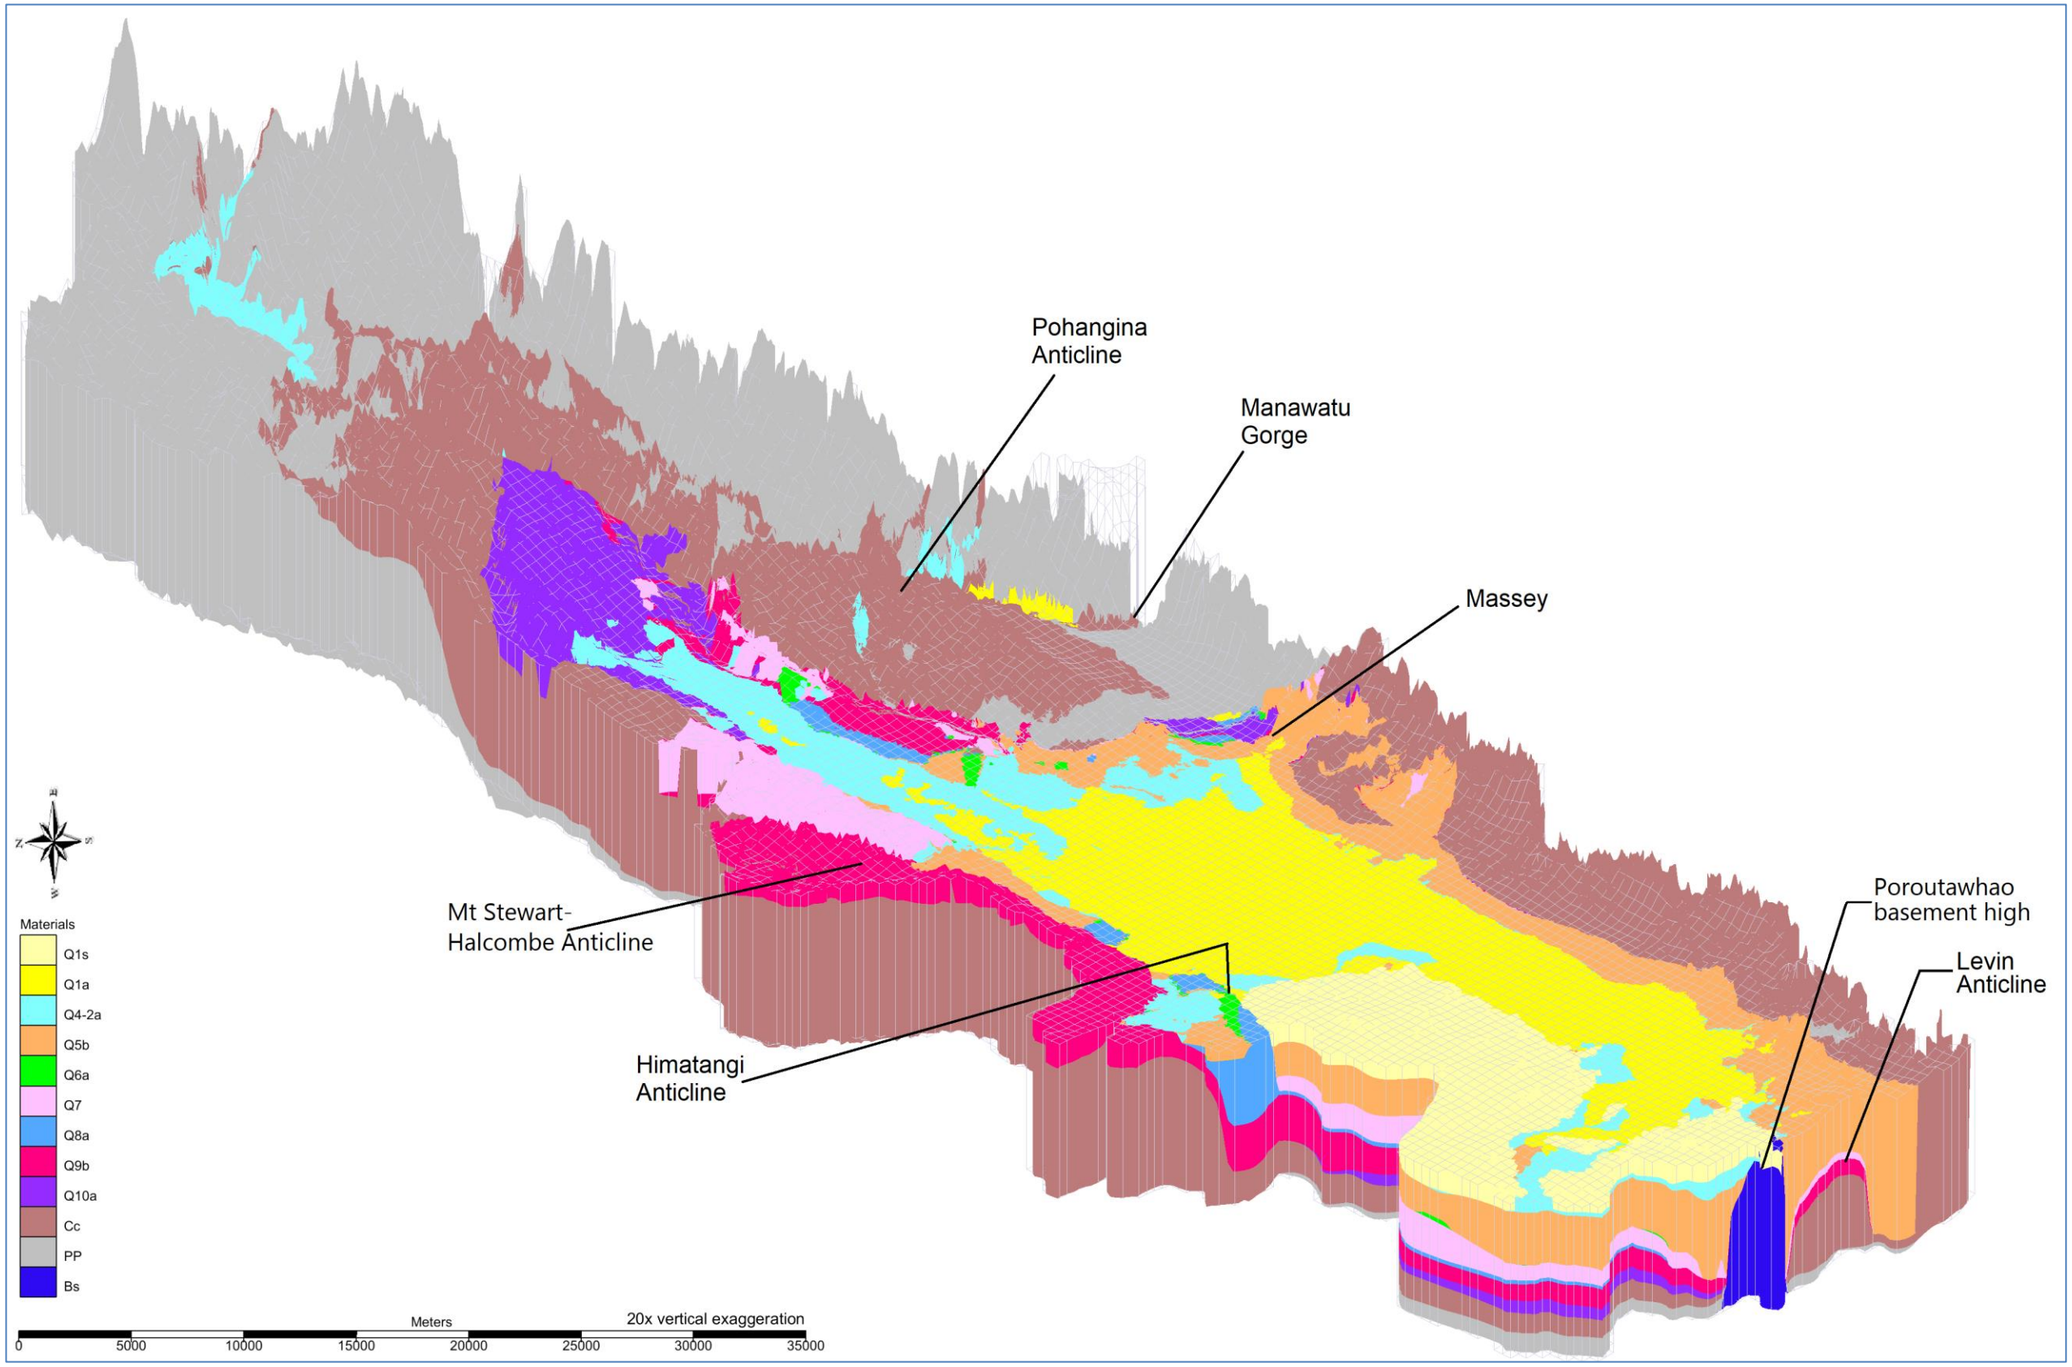

Figure 8-5. Block diagram presenting the stratigraphical framework in the LMC.

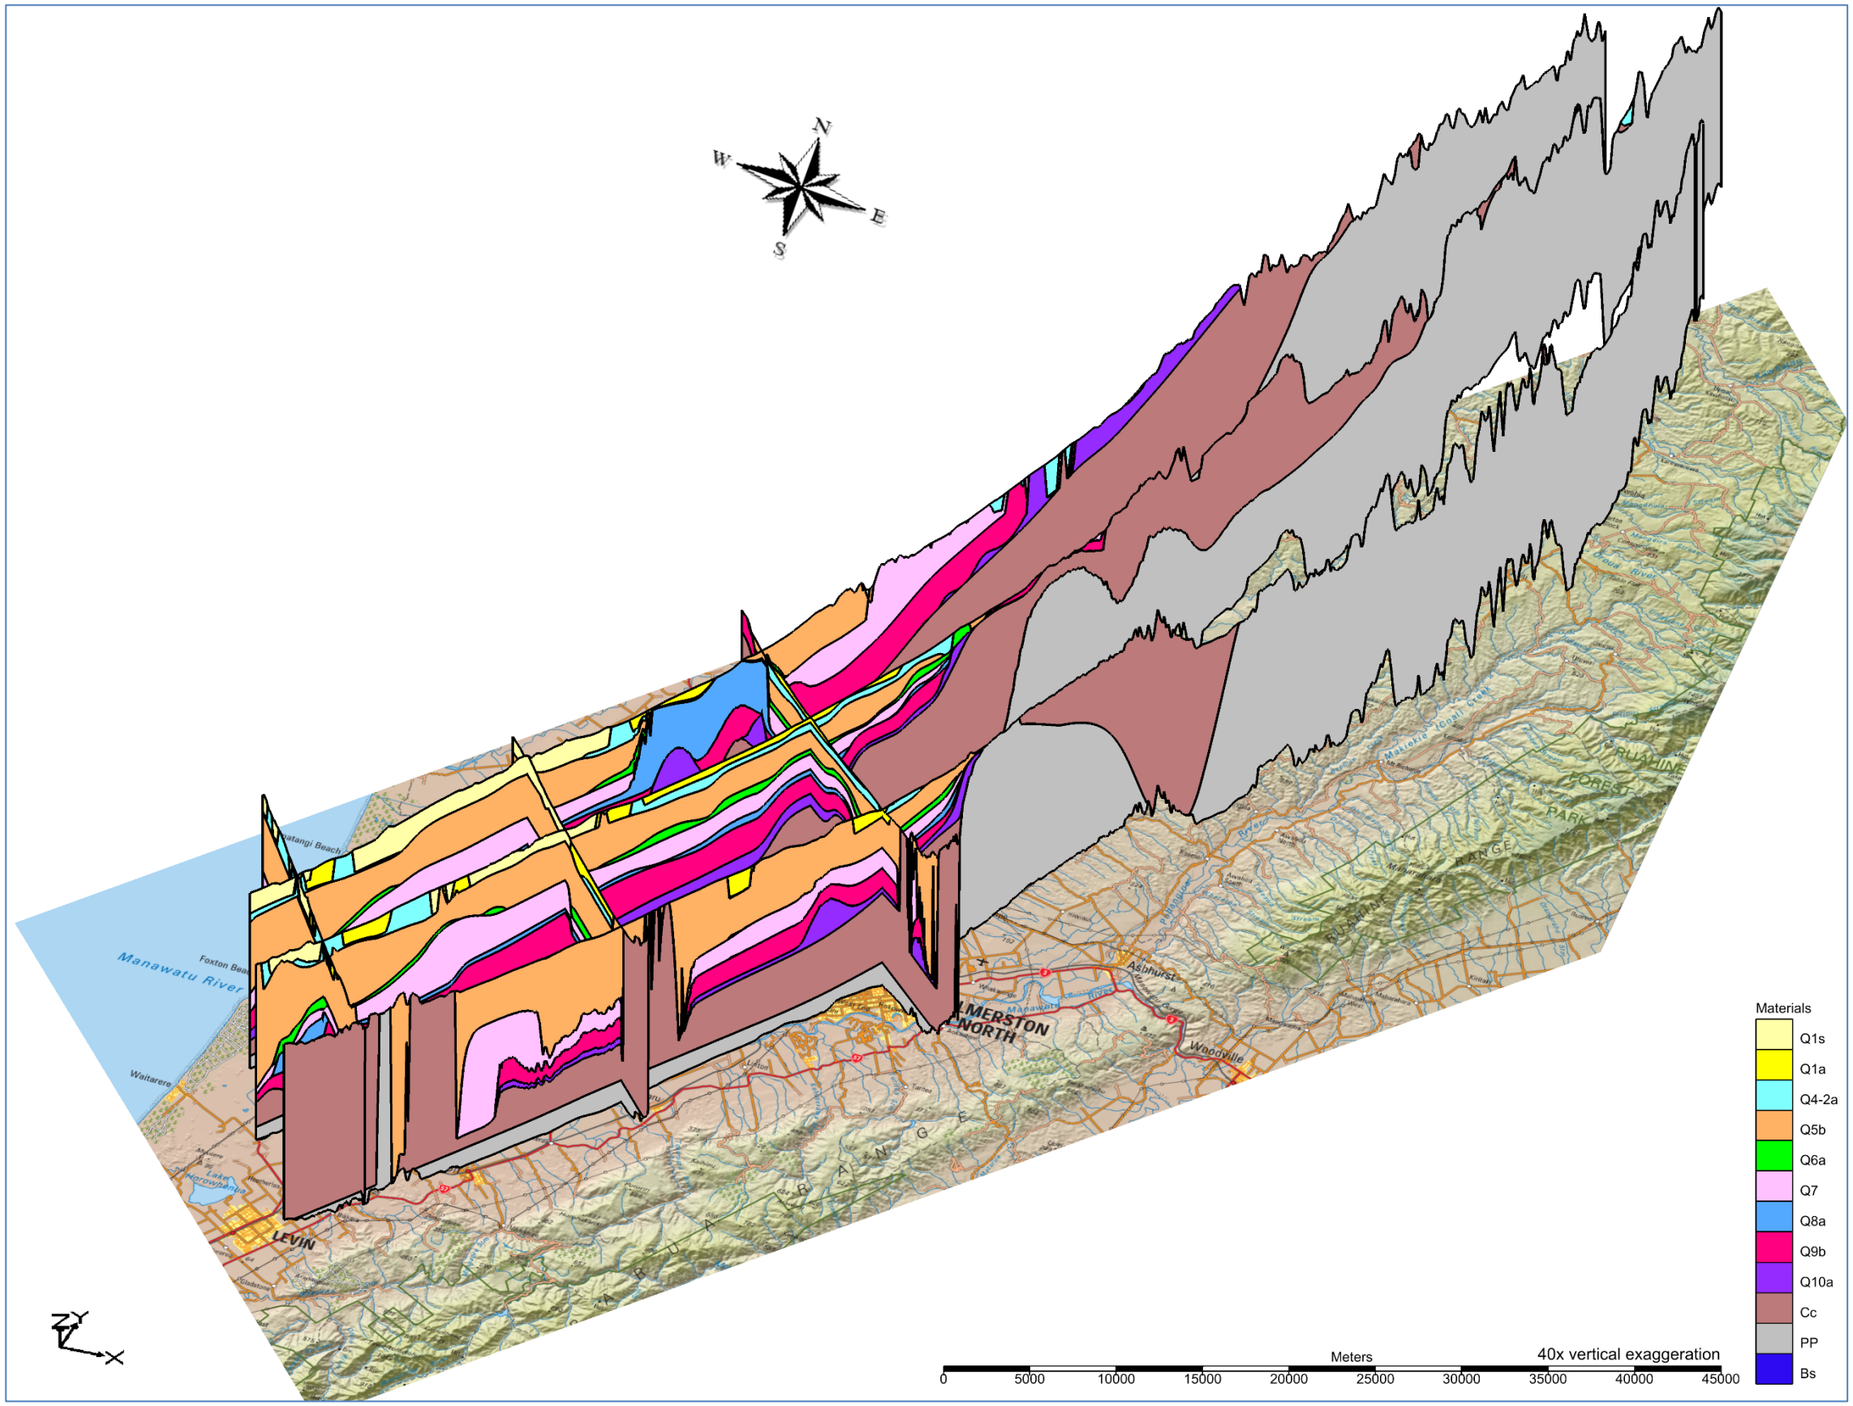

Figure 8-6. Fence diagram presenting the stratigraphical framework in the LMC.

Structure has been critical in controlling river courses through previous cold weather periods, certainly from the Waimaunga Glacial period (OIS8) but possibly also starting from the Nemona Glacial (OIS10). Begg *et al.* (2005) note that folding and faulting in the Wanganui Basin through the Late Castlecliffian to middle Quaternary period (700–128 ka; OIS17–OIS5) have restricted river courses to areas between anticlinal crests for much of that period, and alluvial gravels relating to that period lap against older elevated deposits around the anticline axes. Because of this local deformation, the Pohangina and Oroua rivers have broadly occupied the same courses as today from about OIS10. The stratigraphical model developed in this thesis clearly supports this hypothesis.

8.4 LMC conceptual hydrogeological model

Model conceptualisation entails making simplifying assumptions that reduce the complexity of the modelled system to an appropriate level to enable it to be efficiently simulated. Groundwater conceptual models are commonly presented as a description, graphical presentation or a combination of both. In this thesis, it has been chosen to present the groundwater system conceptualisation through clarifying its main assumptions and highlighting principal uncertainties and limitations.

8.4.1 Assumptions

The LMC groundwater flow system model presented in this thesis is based on the following conceptual assumptions:

1. The groundwater flow system comprises a hydraulically continued sequence of Pliocene–Quaternary deposits, with no mappable aquitards.
2. The lithostratigraphy determines the system's hydraulic properties and structure controls the system's boundaries.
3. Greywacke rocks cropping out in the ranges and underlying cover bed strata represent an impervious hydrogeological basement.
4. Groundwater divides coinciding with hydrological divides separate the hydrogeological system in the LMC area from the hydrogeological systems

in the Rangitikei catchment to the north and the Horowhenua area to the south. No groundwater flow is considered possible through these vertical boundaries.

5. Groundwater flow below 350 mbgl is predominantly horizontal and/or very slow (stagnant), which enables defining the model bottom at that level as a no-flow boundary.
6. Surface water features in the LMC area are hydraulically connected to the underlying groundwater system, with no perching, allowing exchange of water between the hydrological and hydrogeological systems subject to relative hydraulic head conditions and bed material conductance.
7. A regional water table bounds the groundwater flow system from above.
8. The groundwater system is replenished by rainfall and irrigation returns percolating to the water table.
9. The water table does not lose water to the atmosphere directly through evapotranspiration.
10. There is no need to include the unsaturated flow component of the hydrogeological system in the groundwater flow model. Rain recharge and irrigation return inputs into the groundwater system are best obtained from soil moisture calculations (Section 4.7.2).
11. Surface water and groundwater in the LMC ultimately discharge into the Tasman Sea.
12. There is no indication of seawater incursion into the groundwater system, i.e. there is a hydrodynamic balance between fresh groundwater flowing into the Tasman Sea and the saline seawater.
13. Gravity and topography are the main controls on the groundwater flow, which takes place in a general northeast-southwest down catchment direction.
14. The river valleys and plains in the LMC represent a regional groundwater discharge zone.
15. There are no significant seasonal, annual or longer-term changes in the hydraulic head or groundwater quality, which allow for representing the system using long-term average conditions (steady-state).

16. Groundwater flow occurs in porous media equivalent system, to which Darcy's law applies.
17. Literature reported values can be used as initial estimates of aquifer properties for various lithologies.
18. Anthropogenic interferences have little influence on the groundwater flow regime and quality in the area, but abstraction from permitted and consented wells must be considered in hydrogeological analysis and modelling for completeness.

8.4.2 Uncertainty and limitations

The main uncertainty in the above presented conceptual model relates to the assumed no-flow conditions across the vertical projection of the surface water divides between the LMC and the Rangitikei groundwater system to the north and the LMC and the Horowhenua groundwater system to the south. The occurrence of the Poroutawhao Basement High to the south enhances the feasibility of selecting the surface water divide as a southern model boundary. The northern model boundary is more uncertain, however, especially that it can theoretically move with pumping and variation in recharge rates and distribution pattern. Nevertheless, there is no evidence that this has happened in the past and it is believed that it is unlikely to happen in the future.

The adopted conceptual model assumes hydraulic properties heterogeneity across the identified hydrolithostratigraphical units. However, this limitation has been overcome through calibrating the model using pilot point sets specified for individual hydrolithostratigraphical units (Section 8.10.3).

The configuration of the 'solids' that represent the hydrolithostratigraphy is based on Inverse Distance Weighted (IDW), which is one of the most commonly used techniques for geospatial interpolation of point data. The results of this method could be compared in future work with other interpolation methods like Kriging and Natural Neighbour to investigate the most appropriate algorithms for stratigraphical modelling in the LMC area.

Uncertainty relating to observation and production wells screen positions influences the reliability of the calibrated model. To overcome this limitation, additional data on wells should be gathered and incorporated in any future fine tuning of the model presented in this study.

8.5 Groundwater numerical model implementation

Groundwater flow models are described in terms of their spatial and temporal coverage. They can be 1D, 2D or 3D, transient or steady-state. Numerical modelling requires representing or approximating the continuous bulk and series using discrete quantities and periods, respectively. This approach is known as discretisation. Model grids or meshes discretise the continuous natural system into segments (cells, elements or blocks) that allow numerical solutions to be calculated. In transient simulations, the flow equations are discretised through time by steps. Model run times are proportional to the number of spatial segments and time-steps. This aspect becomes particularly critical in model calibration runs where the model needs to be run repeatedly to estimate the most appropriate parameters. Therefore, spatial and temporal discretisation should be fine enough to define the problem adequately but not too small to maintain practical computational requirements.

8.5.1 Temporal discretisation

An important decision that had to be made in the early stages of this research is related to whether a transient model is needed or a steady-state model is fit for purpose (Section 2.1.1). Under steady-state flow conditions, the hydraulic head does not change with time whereas it does under transient flow conditions. Steady-state flow conditions are assumed to be achieved when the hydraulic head and, hence, the magnitude and direction of flow are constant with time throughout the model domain. Transient flow conditions are realised when the magnitude and direction of the flow change with time.

Based on the information presented in Section 6.5.1, it can be assumed that in the long-term the LMC groundwater flow system features steady-state conditions.

Therefore, it has been decided that a steady-state model is adequate to represent average long-term groundwater flow conditions in the LMC.

Assuming steady-state flow conditions is advantageous in groundwater flow modelling as it significantly simplifies the groundwater flow governing equation (Section 2.3). Under steady-state groundwater flow conditions, time is no longer an independent variable and, therefore, the storage term in the groundwater flow equation disappears because there is no change in the amount of water within the model domain. Eliminating the storage term from the groundwater flow governing equation is useful in terms of not just reducing computational time, but also data requirements and associated uncertainty.

Although real steady-state conditions do not exist in nature, steady-state models are used widely (Reilly & Harbaugh, 2004). The LMC hydrological system does not experience significant climatic seasonal, annual, decadal or longer-term variations (Section 4.6.1) and the objectives of this research do not require high-resolution information on the time it takes for the system to respond to new stresses or the behaviour of the system between periods of relative equilibrium. So, it can be safely assumed that the LMC groundwater flow system can be represented by a state of dynamic equilibrium or an approximate equilibrium condition, i.e. a steady-state simulation.

According to Franke *et al.* (1987), steady-state simulations are useful in analysing pre-development (natural) and new equilibrium conditions, and calibration of steady-state models provides information on hydraulic conductivity and transmissivity. Franke *et al.* (1987) argue that because storage effects are not involved in steady-state modelling, its calibration results are often less ambiguous than transient state calibrations.

8.5.2 Spatial discretisation

Reilly and Harbaugh (2004) clarify that simplification of the model domain to one or two dimensions in plan-view or cross-section is commonly undertaken to save

on modelling time and effort. However, such simplification should not compromise the modelling objectives and there should be no or negligible flow orthogonal to the line or plane of the one- or two-dimensional representation of the system. Given the geological and hydrological complexity of the LMC hydrogeological system, 3D (multi-layer) modelling has been decided to be necessary.

The LMC groundwater model domain is defined on hydrological and geological basis. It covers the entire lower Manawatu hydrological catchment except basement rocks outcrop areas. The top of the model domain is defined by the land surface and the bottom of the model domain is defined at 350 mbgl or the basement rock contact, whichever is shallower. The model is based on a 500x500 m finite difference grid, originating from 2,712,000 m Easting and 6,050,000 m Northing on the New Zealand Map Grid, rotated 45° to the north to align it with the principal groundwater flow direction. The model domain covers an area of 112x41 km (4,592 km²), divided into 224 columns and 82 rows. Vertically, the model thickness has been divided into seven layers. Model cells that fall outside the area and/or depth of interest have been inactivated. The LMC groundwater flow model comprises a total of 128,576 cells (56,722 active cells and 71,854 inactive cells).

3D geological models (e.g. Figure 8-5) can be transposed on finite element grid in different ways, including (1) boundary matching, (2) grid overlay, and (3) grid overlay with equivalent hydraulic conductivity (Keq) (Figure 8-7).

Aquaveo (2017) explains that in boundary matching approach, the top and bottom of the grid are deformed to match the tops and bottoms of the stratigraphical model and the interior grid layers are deformed to match stratigraphical boundaries. The grid cell properties are set to match the stratigraphical material coinciding with the grid cell centre. This approach requires determining which grid layers should be associated with which stratigraphical unit. boundary matching produces a close fit between the grid and the stratigraphy, but can result in thin cells that can cause stability or dry cell problems in MODFLOW simulations.

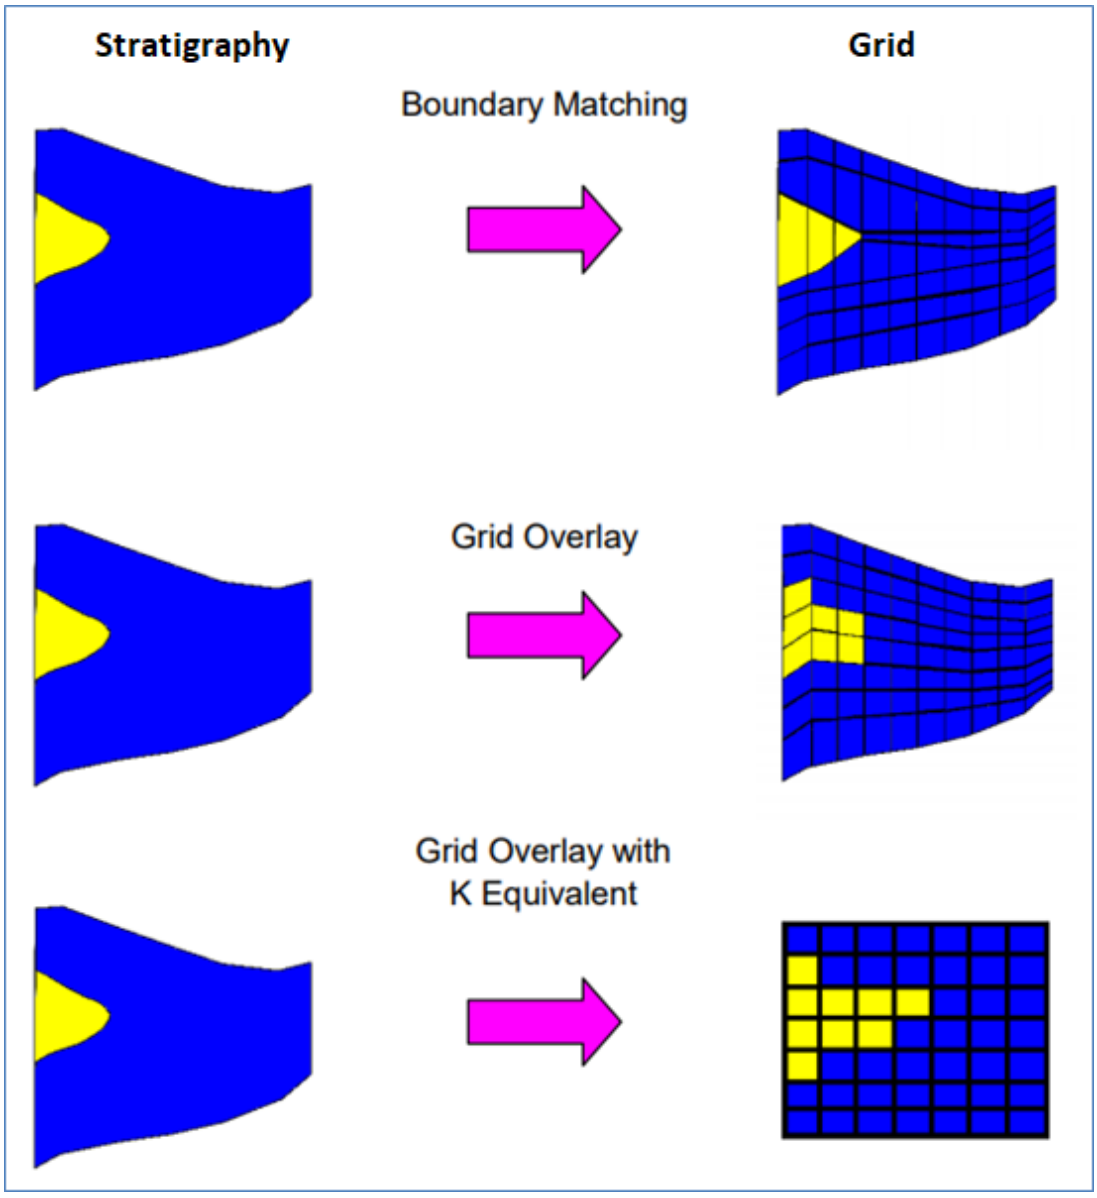

Figure 8-7. Approaches for superimposing stratigraphical models on finite difference grid (after Aquaveo, 2017).

With the grid overlay approach, the top and bottom of the grid is deformed to match the top and bottom of the stratigraphical model and the interior grid layer boundaries are deformed to be evenly spaced between the top and bottom of the grid using a simple linear interpolation without matching stratigraphical boundaries. As with the boundary matching method, the grid cell properties are set to match the properties of the stratigraphical unit at the grid cell centre. This method does not result in as close a fit between the grid and the stratigraphy as the boundary matching method, but it may avoid thin cell problems associated with the boundary

matching approach. The grid overlay option does not require assigning grid layer ranges to each stratigraphical unit.

One of the problems with the grid overlay approach is that if there is a relatively thin layer in the stratigraphical model which does not encompass any cell centres or only few cell centres, the layer will be under-represented in the finite difference grid. This becomes particularly important if the layer is meant to represent a low permeability layer. For such cases, the grid overlay with K Equivalent (Keq) option may give superior results. The grid overlay with Keq method is identical to the grid overlay method in terms of how the elevations of the grid cells are defined but rather than simply assigning cell properties based on the stratigraphy at cell centres, it computes custom horizontal and vertical hydraulic conductivity (Kh and Kv, respectively) values for each cell based on the thickness of each stratigraphical unit in it and computes equivalent Kh, Kv and storage coefficient for the cell. Thus, the effect of a thin seam in a cell would be included in the cell properties.

The LMC groundwater flow models presented in this thesis have been parametrised using the grid overlay approach, through which the stratigraphical model 11 variable thickness units have been superimposed on the seven numerical model layers of unified thickness of 50 m each (Section 8.8).

8.5.3 Model code and software

Based on the discussion presented in Sections 2.6 and 2.7, the LMC has been implemented using MODFLOW 2000 numerical model engine (Harbaugh *et al.*, 2000) and GMS 10.3 graphical user interface for pre- and post-processing of model input data and results. Microsoft Access™ 2016, Microsoft Excel™ 2016 and ArcGIS for Desktop™ 10.4 have been extensively used in data preparation for input in the modelling and in the manipulation of the modelling results.

The LMC model is a steady-state cell centred model. It uses the Layer-Property Flow (LPF) package to specify properties controlling flow between cells. By using this package, the top and bottom elevations, horizontal and vertical hydraulic

conductivity are defined for each layer and MODFLOW computes the cell by cell conductances using the layer geometry and hydraulic conductivity values. The preconditioned conjugate-gradient (PCG) method is used to solve linear and nonlinear flow conditions equations for hydraulic head in the finite difference equations in each step of a MODFLOW stress period.

8.6 Boundary conditions

Hydraulic head and/or hydraulic head gradient must be defined at the periphery of groundwater flow models (Barnett *et al.*, 2012). There are three types of groundwater flow model boundary conditions, specified head, specified flux, and mixed (Table 8-4).

Table 8-4. Groundwater boundary conditions (Barnett *et al.*, 2012; Franke *et al.*, 1987).

Boundary type & general name	Formal name (Bear, 1979)	Mathematical Designation
Type 1 – specified head	Dirichlet	h = constant
Type 2 – specified flux	Neumann	$\frac{dh}{dn}$ = constant, where n is the time level.
Type 3 – mixed boundary condition	Cauchy	$\frac{dh}{dn} + ch$ = constant, where c is also a constant

For specified head boundary condition (Type 1), the head of a boundary cell or node is specified. When the head is specified along a section of the model boundary, the model calculates the flow across this boundary section. For specified head-gradient boundary condition (Type 2), the gradient of the hydraulic head is specified at the boundary, which implies that the flow rate across the boundary is specified. For specified head and gradient boundary condition (Type 3), both the head and the head gradient are specified. This type of boundary condition in groundwater flow models is implemented indirectly by specifying a head and a hydraulic conductance or resistance, both representing effects of features that are located outside the model domain. Examples of such boundary conditions include lakes and rivers overlying confined aquifers where the flow between the aquifer and the lake can be represented by specifying the lake level

and a conductance value related to the bed of the lake or river. The LMC groundwater flow model have been assigned boundary conditions as described below.

8.6.1 The coastline

The LMC groundwater system is in contact with and discharges into the Tasman Sea. There are many ways to represent aquifer coastal boundary conditions, including setting a specified head boundary in all model layers along the coastline, setting a specified head boundary at the topmost layer along the coastline and no-flow boundary in the underlying layers, or extending the modelled aquifer into the sea. In this research, it has been decided to set a specified head boundary along the coastline only in the topmost model layer and no-flow boundary at the perceived groundwater-seawater interface in the other model layers using the Ghyben-Herzberg relation, which describes the position of the interface between the fresh groundwater and the saline seawater in coastal settings. According to Todd and Mays (2005), the Ghyben-Herzberg relation can be written for typical groundwater-seawater[66] interface situation as:

$$z = 40h_f \qquad 8\text{-}1$$

where z is the depth to the groundwater-seawater interface below the datum (mean sea level) and h_f is the groundwater level above the datum as illustrated in Figure 8-8.

Table D-3 in Appendix D shows that groundwater density in the LMC varies from 1,000.065 kg/m³ to 1,002.409 kg/m³. The highest groundwater densities in the LMC and surrounds are found in the Poroutawhao Basement High/Levin Anticline area, not in the coastal area. So, it is safe to assume that Eq. 8-1 can be used to delineate the groundwater-seawater relationship in the LMC near the coastline and approximating the contact between freshwater and seawater as a sharp interface.

[66] Typical density of freshwater (ρ_f) is 1,000 kg/m³ and typical density of seawater (ρ_s) is 1,025 kg/m³.

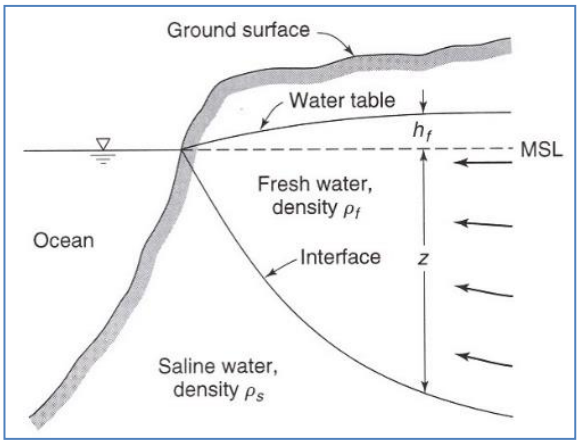

Figure 8-8. Idealised sketch of the relationship between fresh groundwater and seawater in an unconfined coastal aquifer (after Todd and Mays, 2005).

The flow across the groundwater-seawater interface is considered negligible. So, no-flow boundaries have been applied to model layers 2 through 7 at the saltwater interface. The location of the interface in these layers have been approximated using the Ghyben-Herzberg relation and the piezometric map presented in Figure 6-8. Model domain cells seawards of the interface have been inactivated. MODFLOW 2000 'CHD1 – Time-Variant Specified Head' package has been used to simulate the coastline boundary in the model's topmost layer.

8.6.2 Water divides and basement rocks

A no-flow boundary condition implies that the component of flux in the direction normal to the boundary is zero, i.e. the head gradient normal to the boundary is zero ($\partial h/\partial n = 0$). A no-flow boundary condition has been defined at the bottom of the model as delineated in Section 8.5.2 and along the contact between the Pliocene-Quaternary deposits and the greywacke basement rocks of the axial ranges. The groundwater divide that is assumed to coincide with the surface water divide has also been set as no-flow boundary.

8.6.3 The water table

The top boundary for the LMC groundwater flow model is defined by the water table, which is conceptualised as a free surface recharge boundary that is not subject to losses by evaporation and transpiration. Recharge to the water table is specified as calculated in Section 4.7.2 (Figure 4-18). MODFLOW 2000 'RCH1 – Recharge' package has been used to simulate the influx into the water table.

8.6.4 Surface water features

Surface water features are not only important as groundwater flow model boundaries, but their flow data can also be useful in model calibration. The LMC comprises rivers, streams, drains, wetlands, lagoons and lakes. In a catchment-scale model such as that presented in this thesis, not all such features need to be incorporated. Commonly, Type 3 mixed boundary condition settings are used to represent surface water features in groundwater flow models. MODFLOW 2000 'RIV1 – River' package has been used to simulate rivers and streams in the model and the 'DRN1 – Drain' package has been used to simulate the coastal lakes.

Bed conductance (C) is an important parameter in the 'RIV1 – River' and 'DRN1 – Drain' packages. It is expressed in units of L^2/T and defined as

$$C = \frac{k}{t} lw \qquad 8\text{-}2$$

where k is the hydraulic conductivity [L/T], t is the thickness of the material in the direction of flow [L], and lw is the cross-sectional area perpendicular to the flow direction [L^2]. Conductance can be calculated for linear and areal features such as streams and lakes, respectively.

The modelling graphical user interface used (GMS) automatically calculates the lengths of arcs (linear features) and areas of polygons (areal features).

Therefore, conductance for rivers and streams for input into the model through the GMS GUI is required to be in terms of conductance per unit length

$$C_{\text{arc}} = \frac{k}{t} w \qquad 8\text{-}3$$

where C_{arc} is conductance per unit length [L/T], t is the thickness of the material [L], and w is the width of the material along the length of the arc [L].

Conductance for lakes for input into the model through the GMS GUI is required to be in terms of conductance per unit area

$$C_{\text{poly}} = \frac{k}{t} \qquad 8\text{-}4$$

where C_{poly} is conductance per unit area [1/T] and t is the thickness of the material [L].

Initial conductance values have been estimated for modelled surface water features (Figure 8-9), but they have been refined during model calibration (Section 2.9).

8.7 Groundwater abstraction

Information on groundwater abstraction rates and the position of wells is needed for the groundwater flow model. In the LMC, it is permitted to take up to 50 m³/d of groundwater without resource consents (licence) from wells not deemed connected to surface water providing they meet conditions set in the regional plan. Wells considered connected to surface water are allowed to abstract up to 15 m³/d without resource consent. In 2016, there were records of c. 4,600 wells in the LMC, of which c. 260 well had resource consents to abstract water (Figure 8-10). Groundwater abstraction has been incorporated in the LMC groundwater flow model using the MODFLOW 2000 'WELL1- Well' package and screen extent data.

8.7.1 Well depths and screen lengths

Within the LMC groundwater flow model domain, the depth of c. 3,530 production wells is known but screen length is known for only c. 690 wells. Well depth and screen extent information needs to be estimated for the groundwater flow model. For wells with known depth, the average depth is 48.75 m and the median depth is 30 m. For wells with screen data, the average screen length 4.5 m and the median screen length is 3 m. Therefore, wells that have no depth information have been assumed to be 30 m deep and a screen length of 3 m has been assumed for wells that do not have that data. There are c. 70 wells that are shallower than 3 m. They have been excluded from the model.

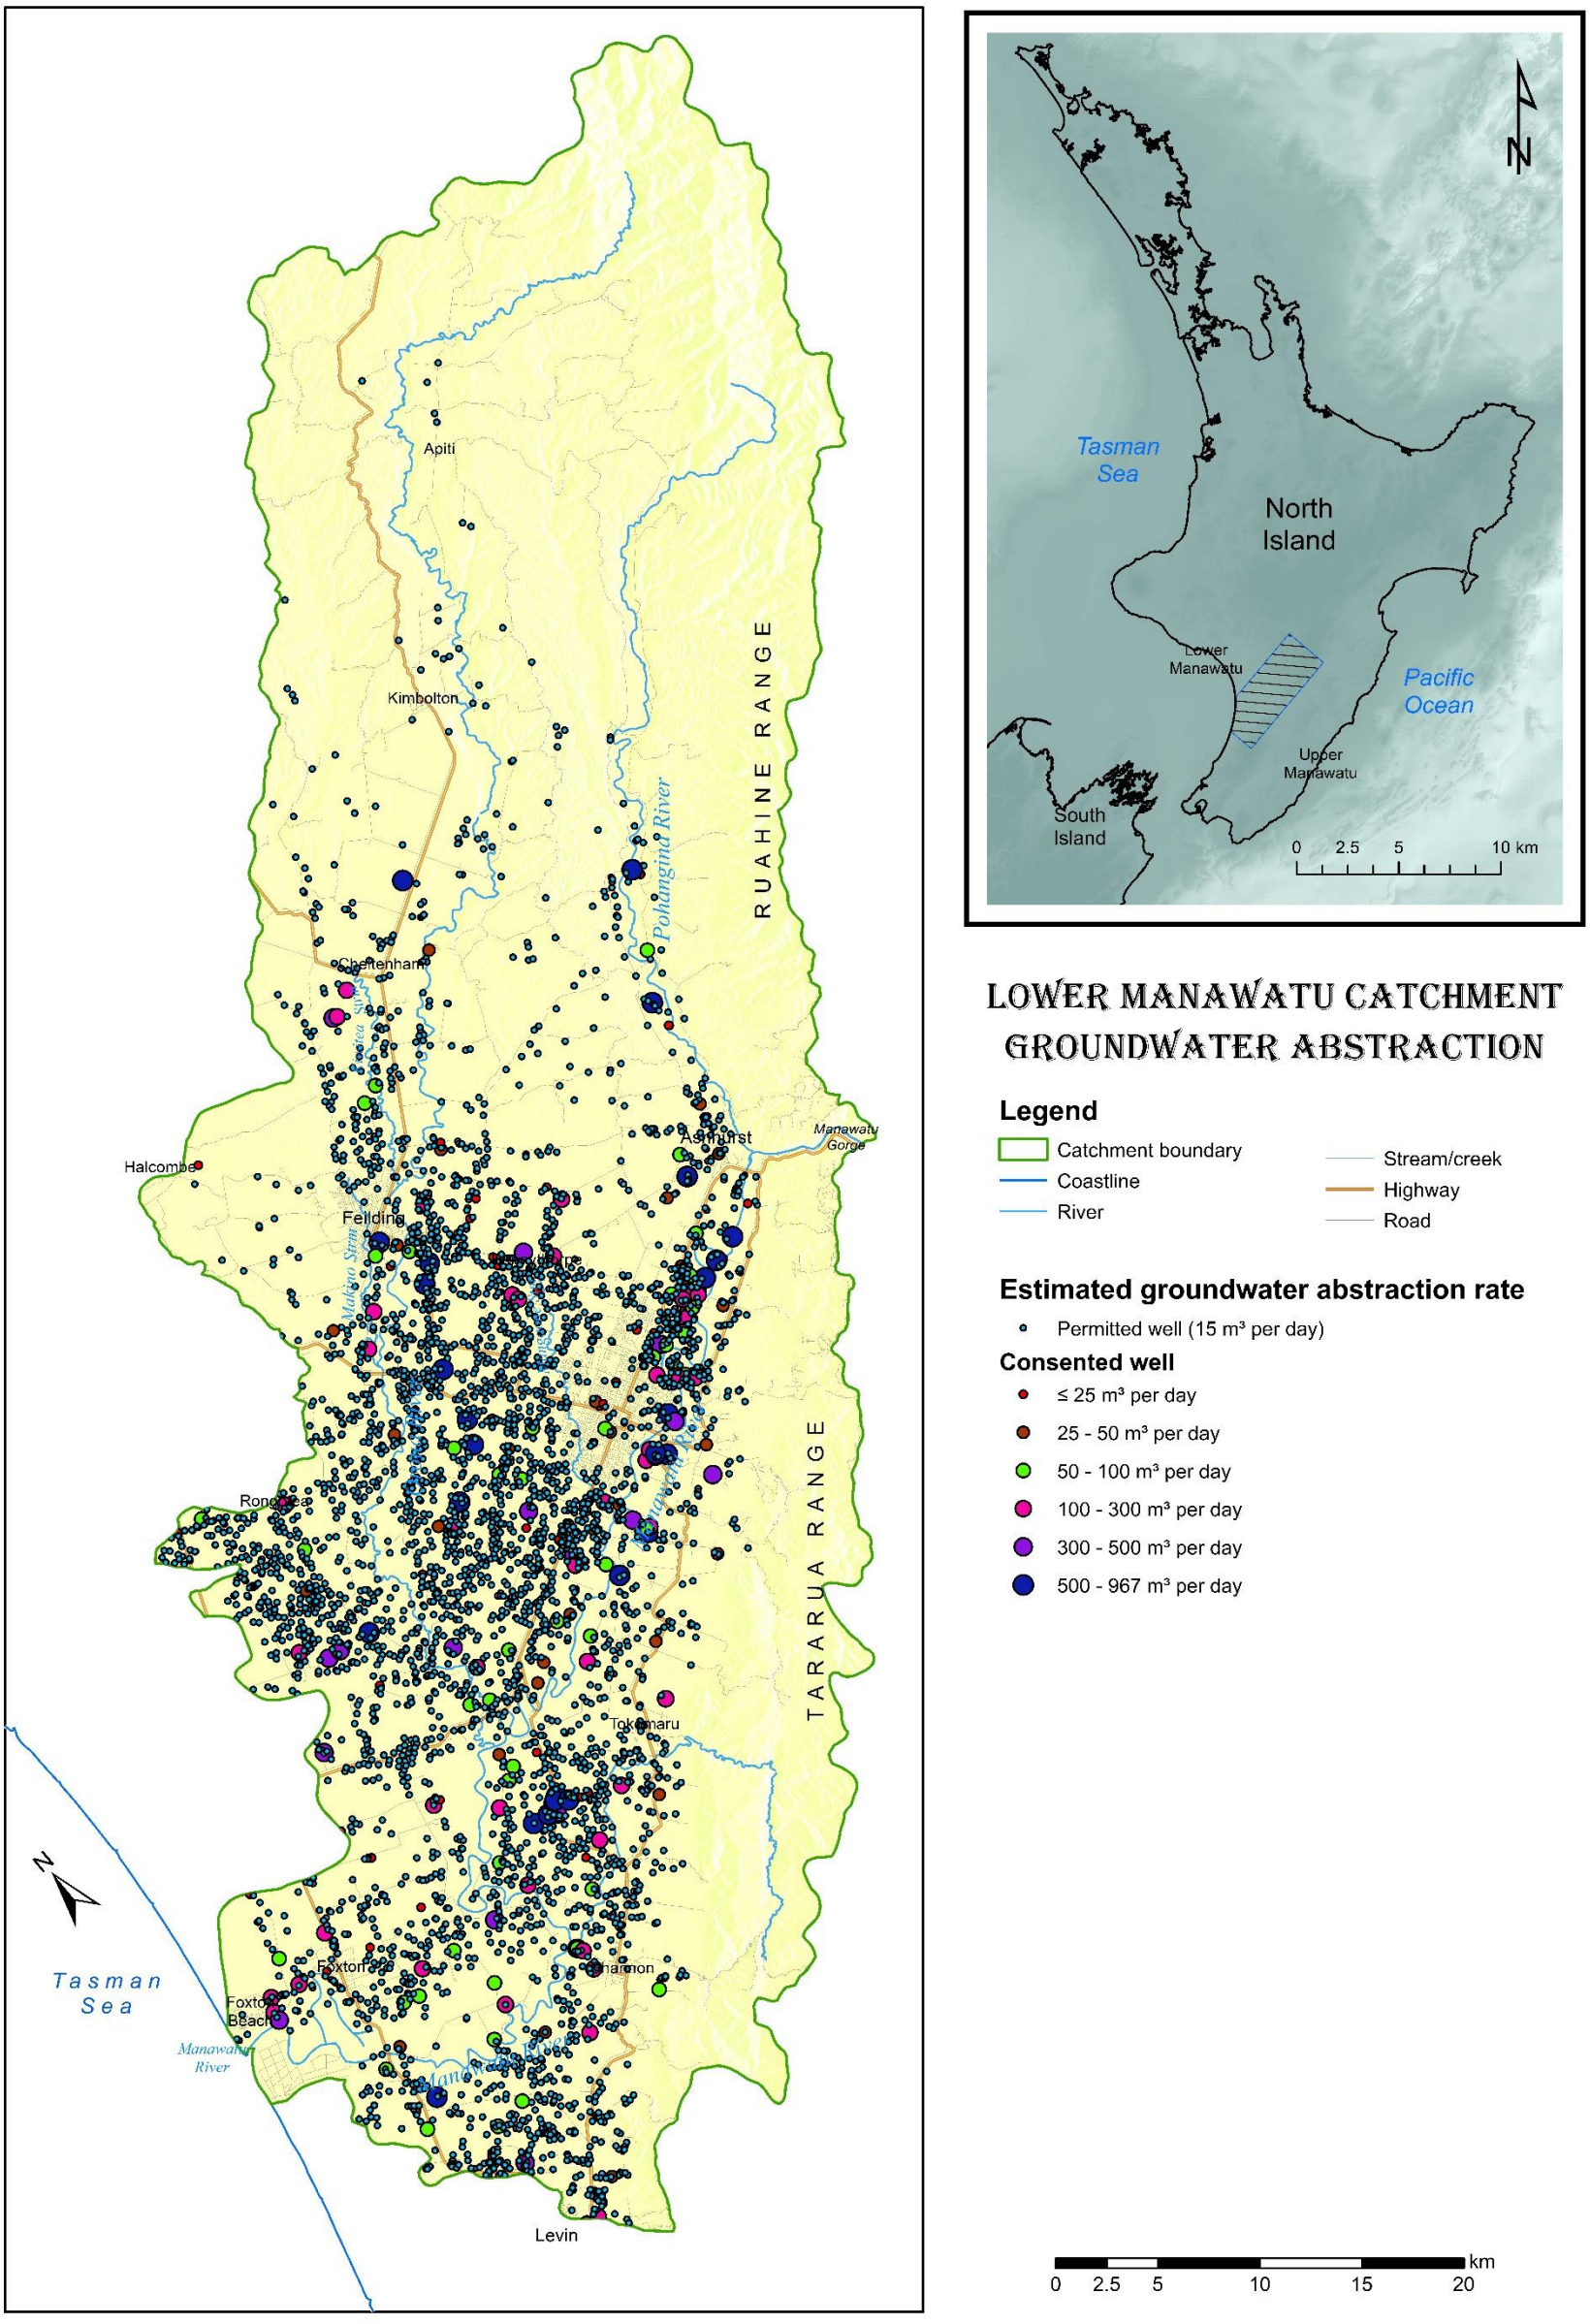

Figure 8-10. Average groundwater abstraction rates included in the groundwater flow model.

8.7.2 Pumping rates

There are no data on groundwater abstraction in the LMC. Zarour (2008) developed a method to estimate abstraction in the Manawatu–Wanganui region assuming that on average permitted wells take 15 m³ per day throughout the year, and consented wells are pumped 100 days per year at 80% of their maximum consented daily take volume. This approach has been adopted to estimate groundwater abstraction in the LMC numerical groundwater model.

8.8 Model parametrisation

Groundwater flow models use hydraulic conditions and properties in head computations. Initial best estimates need to be input in the model, which can later be adjusted to better suit field observations. There are various methods to assign hydraulic properties to model cells. Hydraulic conditions and properties can be assigned unvaryingly to the entire model domain, to zones within it, or to individual cells. Over–parametrisation is often tempting, but should be avoided as much as practically possible just like the case with over–discretisation.

Due to the heterogeneous nature of most geological material, determination of parameter distribution in a groundwater flow system is one of the most difficult aspects in hydrogeological modelling. In approaching this question, the modeller should maintain the mindset that the objective is to represent the main features in the modelled system rather than replicating it. In this context, upscaling is obligatory and equivalent parameters need to be found to represent the modelled system and enable reproducing its behaviour.

The hydrolithostratigraphical model presented in Section 8.3.3 has been overlaid on the model domain described in Section 8.5.2, deforming the top and bottom of the grid to match the tops and bottoms of the solids that represent the various units in the hydrolithostratigraphical model and the interior grid layer boundaries have been deformed to be evenly spaced between the top and bottom of the grid. The interior grid layers have not been changed to match the stratigraphical boundaries. The grid cells have been assigned material from the hydrolithostratigraphical model

and parametrised with hydraulic properties of the material that coincide with their centres. Horizontal hydraulic conductivity for the model material have been initially assigned according to Table 8-3. The model materials have been assumed to be horizontally isotropic ($K_x/K_y = 1$) but vertically anisotropic ($Kh/Kv = 10$).

In addition to populating initial horizontal and vertical hydraulic conductivities, initial bed conductance values have been assigned to river and drain model cells based on the estimates presented in Figure 8-9. Initial estimates of horizontal and vertical hydraulic conductivities and conductance values have been changed during the model calibration stage.

8.9 Initial conditions

In addition to having to define hydraulic head and/or hydraulic head gradient conditions along the flow domain periphery, solving the groundwater flow governing equation using the finite difference method requires defining initial head values at each grid cell in the finite difference grid. Initial conditions refer to the distribution of hydraulic head at the beginning of the simulation and, thus, represent boundary conditions in time. In time-independent steady-state modelling, initial conditions do not affect the outcome of the simulation. However, good choice of initial head conditions reduces the number of required iterations for model convergence. In transient models, initial conditions strongly affect the outcome of the models. Transient models commonly use calibrated steady-state model results to provide them with their initial conditions. Initial model heads have been set at the model grid top elevations.

8.10 Set up and calibration

In this research, three steady-state numerical groundwater flow model versions have been produced for the LMC, specifically:

1. Manually calibrated model assuming homogeneous geological strata (Section 8.10.1)

2. Automatically calibrated model assuming homogeneous geological material (Section 8.10.2)
3. Automatically calibrated model assuming heterogeneous geological material (Section 8.10.3).

The three versions of the LMC model represent stepped-up appreciation of the catchment's actual hydrogeological characteristics.

Only hydraulic properties relevant to steady-state conditions have been manipulated in the LMC groundwater flow model calibration, namely, horizontal hydraulic conductivity, horizontal hydraulic conductivity, vertical anisotropy and river and drain bed conductance. It has been assumed that the recharge estimates presented in Section 4.7.2 are reasonably trustworthy and should not be changed during model calibration. So, no flux adjustments have been attempted in the model calibration.

Observations used in model calibration included average groundwater level data presented in Appendix C and surface water losses and gains reported in Section 5.10 and summarised in Table 8-5. Positive groundwater flux values in Table 8-5 indicate groundwater gains and negative values indicate groundwater losses.

Table 8-5. Surface water calibration targets[67,68].

Calibration target code	System/ description	Input point/s	Output point/s	Total input	Total output	Groundwater Flux[69]
TK1	Tokomaru River	R14	R15	204,885	201,267	3,618
TK2	Tokomaru River	R15	R16	201,267	116,057	85,210

[67] All units in mcm/y.
[68] See Figure 8-9 for input and output point locations.
[69] Positive values indicate surface water loss, negative values indicate surface water gain.

For model calibration purposes, groundwater level standard deviation values have been calculated and directly input in GMS. For surface water, 10% of the flux values has been specified as the calibration target interval and GMS calculated the corresponding standard deviations.

Where available, well screen data have been used in model calibration against groundwater head targets. Where that information has not been available, screen extents and positions have been estimated following the method described in Section 8.7.1.

Accurate top of well elevation data are available from surveys for all the groundwater level monitoring wells used in the model as calibration targets, but some of these wells lack screen and/or depth data. Subsequently, confidence levels have been assigned to groundwater level observations as follows:

1. 95% for groundwater level observations from wells with screen data
2. 75% for groundwater level observations from wells without screen data but with known depth
3. 50% for groundwater level observations from wells without screen or depth data.

The confidence interval for flux calibration targets taken from Table 8-5 has been set to 75%.

8.10.1 Initial parametrisation and manual calibration

The LMC groundwater flow model calibration targeted reproducing average groundwater heads and groundwater-surface water interaction conditions within the observed standard deviations at various sites across the catchment.

The LMC groundwater flow model incorporates 11 hydrolithostratigraphical units (Table 8-3). Assuming hydraulic properties homogeneity within each of these units, the model has been parameterised using initial hydraulic conductivity values

presented in Table 8-3 and conductance values presented in Figure 8-9. Manual calibration of the model has been undertaken to refine the initial parameter estimates. The adopted hydraulic conductivity values and ranges presented in Table 8-3 are conformable with those assigned to similar units in the Kapiti Coast groundwater model (Gyopari *et al.*, 2014). The manually calibrated model produced acceptable results (Figure 8-11), largely matching the general piezometric pattern presented in Figure 6-8 and mostly exhibiting surface water-groundwater interaction conditions in line with the picture presented in Section 5.10.

The fit between calculated and observed groundwater heads presented in Figure 8-12 shows extraordinarily reasonable fitness for a manually calibrated, catchment-scale model.

The model fitting statistics and water budget elements presented in Table 8-6 suggest that the manually calibrated model reasonably represents the groundwater system. The simulation shows areas in the upper model layers that are dry (head below bottom of cells) or flooded (head above top of cells) (Figure 8-11). Dry cells in the model coincide with topographically elevated areas like the crests of the Feilding Anticline and Pohangina Anticline where the water table is deepest. So, dry cells are found where they are expected and reflect actual conditions. Flooded cells occur in river valleys and low-lying areas, which is understandable and expected. It must be noted, however, that dry and flooded cells marked by GIS analysis are not only subject to model performance, but they are also related to the resolution and accuracy of the used DEM, model discretisation, the accuracy of land elevation and groundwater head spatial interpolation, and the model resolution.

Initial manual synthesis of the model involved adjusting some cell bottom elevations to allow them to accommodate river boundary conditions, making sure that both the stage and bottom of the river cells are above the cell bottom elevation. Manipulation of the manually parametrised and calibrated model provided important information for the following stages of automated parameter estimation and model

calibration, including the setup of initial head conditions and initial values and ranges for the model parameters.

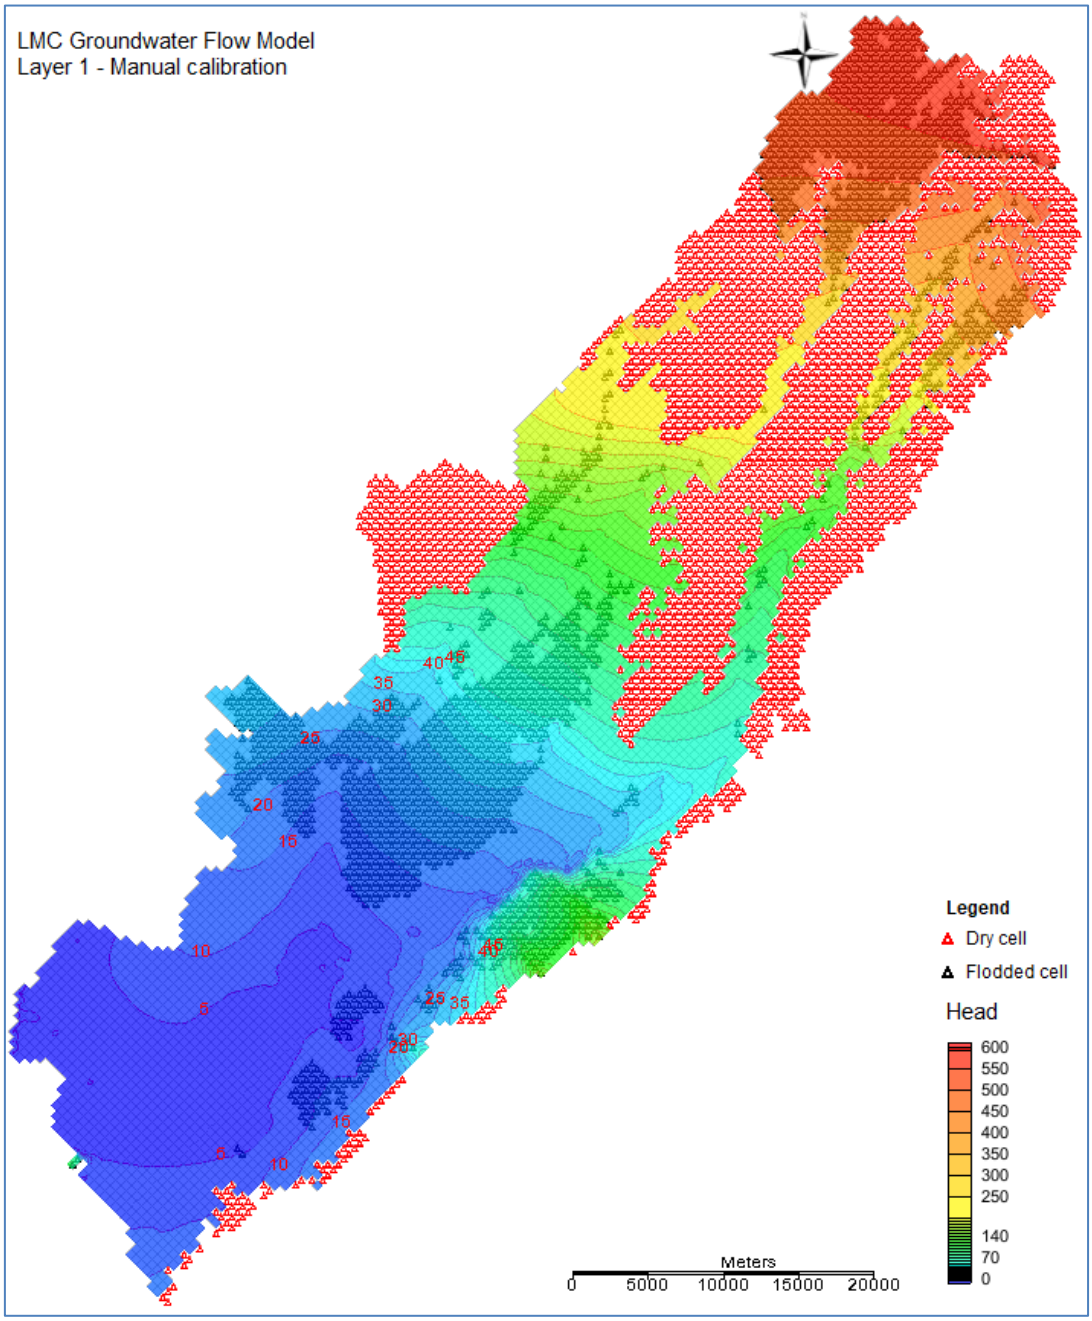

Figure 8-11. Model calculated head distribution (in masl) for the topmost layer from manual calibration.

Used hydraulic conductivity values are presented in Table 8-3 and conductance values are presented in Figure 8-9.

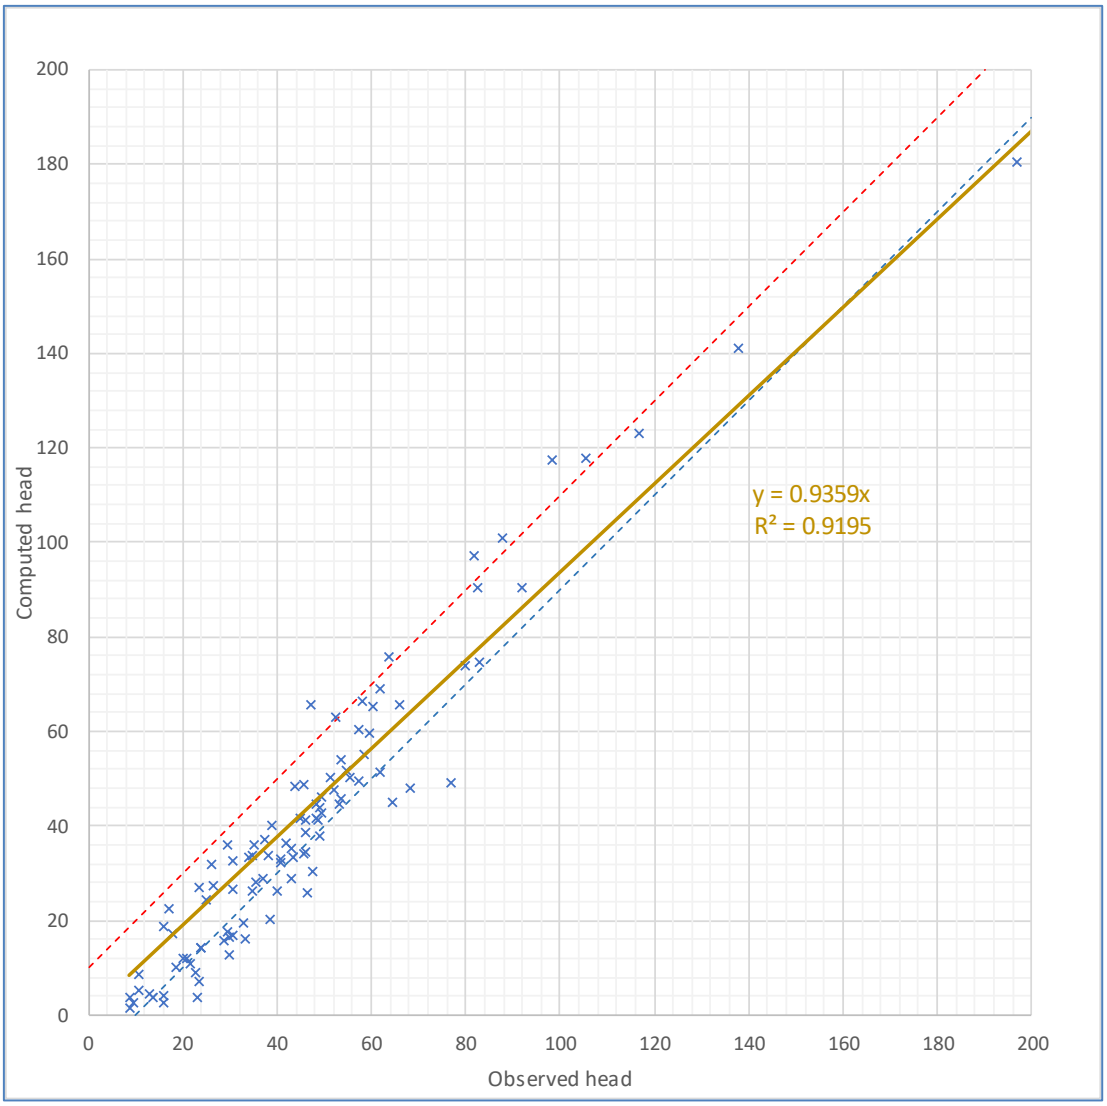

Figure 8-12. Scatter plot of measured heads against manually calibrated model calculated heads using initial estimates of hydraulic conductivity values presented in Table 8-3 and river/stream bed conductance values presented in Figure 8-9.

The brown solid line represents the data linear trend, the red dashed line represents 10 m model overestimation, and the blue dashed line represents 10 m model underestimation. The trend line equation and linear regression goodness-of-fit (R^2) are shown on the graph.

8.10.2 Homogeneous layers calibration and parameter sensitivity

The initial manually calibrated model was followed by automated parameter estimation using PEST 14.0 software (Doherty, 2015) through the GMS GUI. This has been intended to mathematically enhance the initial estimates of hydraulic properties and evaluate model parameter sensitivity. In this process, PEST was run to estimate a 'representative bulk equivalent' hydraulic conductivity value for each of the hydrolithostratigraphical units identified in Table 8-3. Overlaying the stratigraphical model presented in Section 8.3.3 on the groundwater flow model finite difference grid resulted in zonation of the grid cells (Figure 8-13). A reasonable agreement has been achieved between observed and calculated heads from this stage of modelling (Figure E-1 in Appendix E). Model parameters estimated using PEST for this set up are presented in Table 8-7. Maps showing the automated estimates of hydraulic conductivity for the various model layers are presented in Appendix E (Figures E-2 through E-8). Table 8-8 presents the water budget components calculated from this stage of modelling and model calibration metrics.

During the zonal model calibration process, the quality of observation data proved to be challenging, hindering PEST's runs, especially in terms of apparently inaccurate screen extent information. Problematic observation wells have been identified and their data have been excluded from the automated model calibration.

The wells used in automated parameter estimation are listed in Table E-1 in Appendix E.

The automated parameter estimation code PEST enables the evaluation of the sensitivity of the model to input parameters, which is important to assess whether the conceptual model needs revision and/or initial conditions and parameter estimates need adjustment. Sensitivity analysis also helps the users of the model to understand the uncertainties inherent in the model calibration.

Figure 8-14 graphically represents parameter sensitivities obtained from the PEST optimisation process assuming homogeneous geological strata. As explained by Gyopari *et al.* (2014), following the calculation of the Jacobian matrix for each iteration PEST calculates the composite sensitivities for the parameters, then multiplies the composite value for each parameter by the magnitude of the log of its value to obtain relative sensitivity for each parameter. Evaluation of the relative sensitivities enables comparing the effects of different parameters of different magnitude on the results of the model calibration. Figure 8-14 suggests that in the zonal (homogeneous) model calibration process, riverbed conductance parameters have not been relatively sensitive (<0.1), whereas hydraulic conductivities of interglacial times material are relatively moderately sensitive (>0.1) and the hydraulic conductivities for the Plio-Pleistocene and Castlecliffian strata are most relatively sensitive (>0.4). This could be due to the fact that Plio-Pleistocene, Castlecliffian and interglacial times material comprise the bulk of the model volume and, therefore, they have the potential to exert huge influence on the model results.

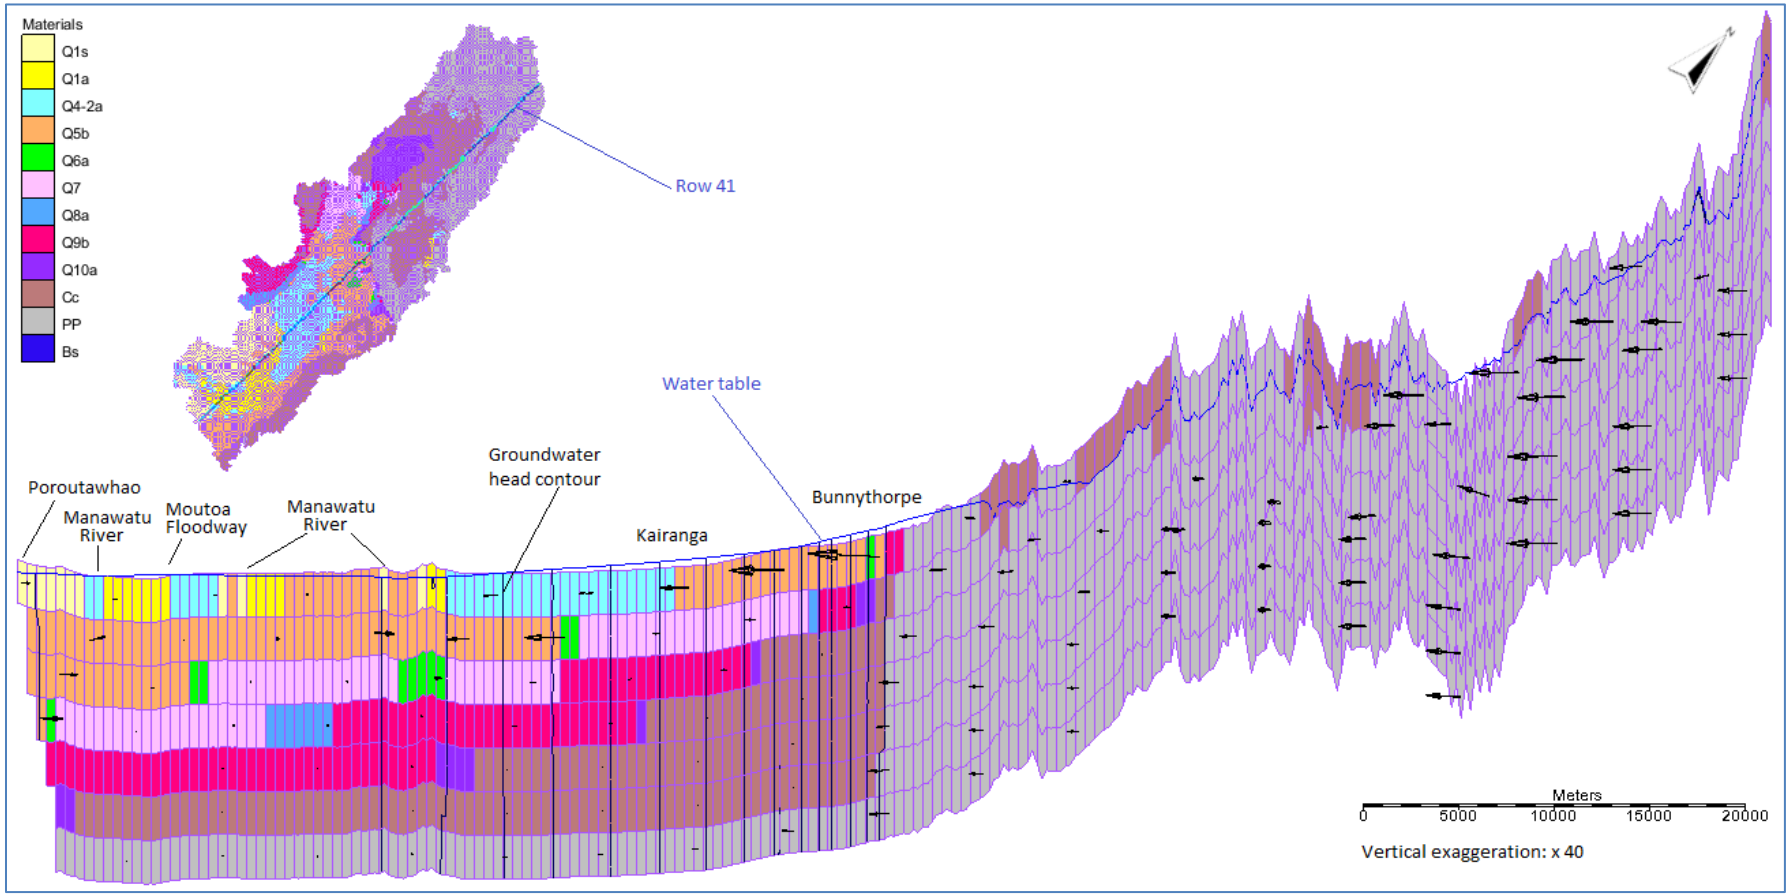

Figure 8-13. Cross-section through row 41 in the homogeneous stratigraphical strata model showing the overlay of geology on the groundwater flow model finite difference grid, flow velocity vectors (black arrows) and the water table (Blue line).

8.10.3 Heterogeneous layers calibration and parameter sensitivity

Knowledge of the lithology of the stratigraphical sequence in the LMC from outcrops and well logs indicates that the strata are heterogeneous. For example, an alluvial unit can in locations comprise coarse sand and gravel with hydraulic conductivity

in the order of 250–500 m/d, but in other places it could consist of clay-bound gravel and sand, characterised by hydraulic conductivity in the order of 1–20 m/d. Consequently, it has been decided to incorporate heterogeneity in automated parameter estimation for the various hydrolithostratigraphical units recognised in the LMC area utilising the pilot points calibration technique in specified zones corresponding to identified lithostratigraphical units. The concept adopted simply allows for spatial variability of hydraulic properties within set limits through each of the hydrolithostratigraphical units overlaid onto the finite difference grid rather than assigning constant parameter values for each of these units. This approach respects both the broad differences between geological distinct units (e.g. Q4-2a versus Q5b) and the variability within individual units. To implement this solution, initial estimates and acceptable ranges of hydraulic conductivity have been set for each hydrolithostratigraphical unit at 25 pilot points across the LMC area (Figure E-9 in Appendix E) based on the first stage of automated parameter estimation and PEST has been used to estimate hydraulic properties at these points and between them for every hydrolithostratigraphical unit as it occurs across the groundwater flow finite difference grid. This approach resulted in good fit between calculated and observed heads (Figure 8-15 and Figure D-9 in Appendix D). Table 8-9 presents the hydraulic conductivity ranges estimated for various hydrolithostratigraphical units in the LMC using zoned pilot point calibration and Table 8-10 presents the calculated elements of the water budget and model metrics from the zoned pilot points calibration. The model suggests that hydraulic conductivity ranges from less than 0.01 m/d to 115.7 m/d through the simulated stratigraphical sequence. Figures E-10 through E-16 in Appendix E portray the estimated hydraulic conductivity values for the LMC groundwater flow model layers and the heads calculated in them.

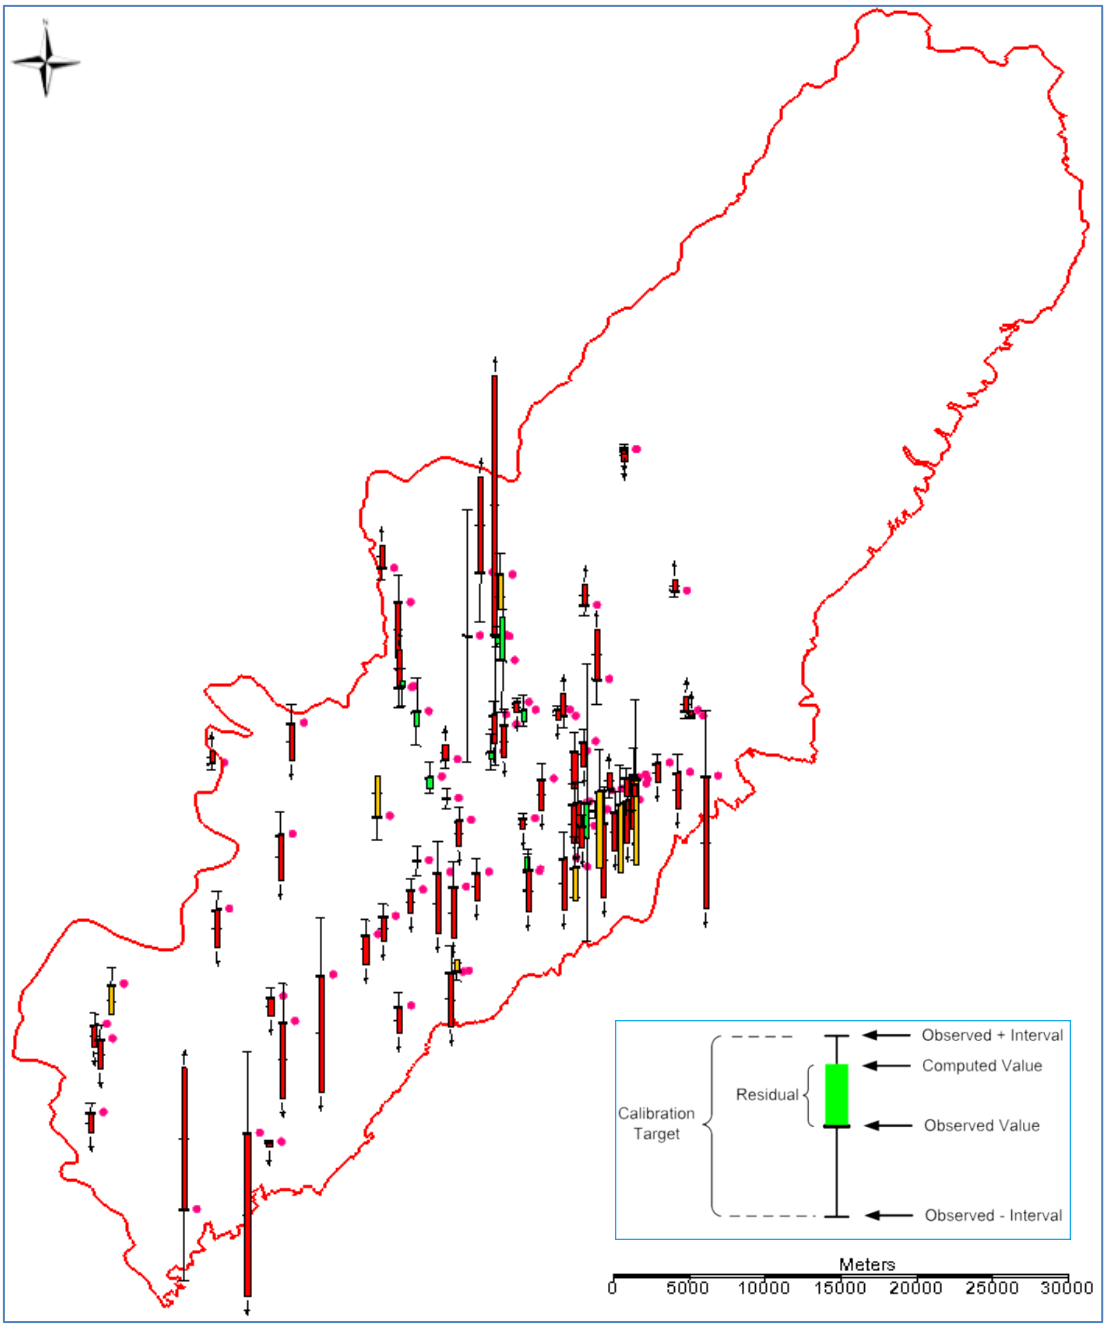

Figure 8-15. Error bars at observation points showing the degree of fitness between calculated and observed heads from automated parameter estimation assuming heterogeneity of hydrolithostratigraphical units within the LMC model area.

Green colour code means the calculated value falls within the calibration target, yellow means that the calculated value is outside the target range but the error is less than 200%, and red denotes that the error is greater than 200%.

Pilot point calibration is extremely demanding in terms of computing resources even for steady-state simulations. So, to keep model run times practical, Singular Value Decomposition (SVD) and SVD-Assist PEST functionalities have been utilised in the zoned pilot point calibration of the LMC groundwater flow model. The SVD process analyses the parameters that are part of a parameter estimation process and

removes parameters that are not helping to solve the problem. SVD-Assist is particularly advantageous for models that have a large number of parameters, e.g. models using pilot points. SVD-Assist helps shorten run times. When using it, PEST runs MODFLOW once for every parameter to compute a matrix and uses that information to create super parameters that are combinations of the parameters originally specified and create a new PEST control file that enables the software to use significantly fewer MODFLOW runs for each of the needed iterations, commonly reducing the number of runs required for each PEST iteration by an order of magnitude.

Simulation of heterogeneity in hydrolithostratigraphical units has been controlled through the application of the Tikhonov regularisation, which provides prior information equations for pilot points to PEST. Tikhonov preferred homogeneous regularisation imposes a homogeneity constraint on the pilot points so that in absence of other information pilot points that are near to one another are set to about the same value. Tikhonov preferred value regularisation was also used to include prior information equations that constrain the pilot points near their starting values. The starting values were assigned to pilot points based on the hydraulic conductivity estimates provided in Table 8-3 and PEST was set to only change those values to calibrate the model if necessary.

Parameter sensitivity plots presented in Figure 8-16 suggest relatively large uncertainty in the assessment of hydraulic conductivity of the Castlecliffian and Plio-Pliocene units in the Pohangina Anticline area, which is understandable given the lack of knowledge about the hydraulic properties of these geological units, particularly in that area, in addition to structural complexities that may affect their hydrogeological parameters. The model seems not to be very sensitive to river bed conductance parameters, possibly due to the scale of the simulation.

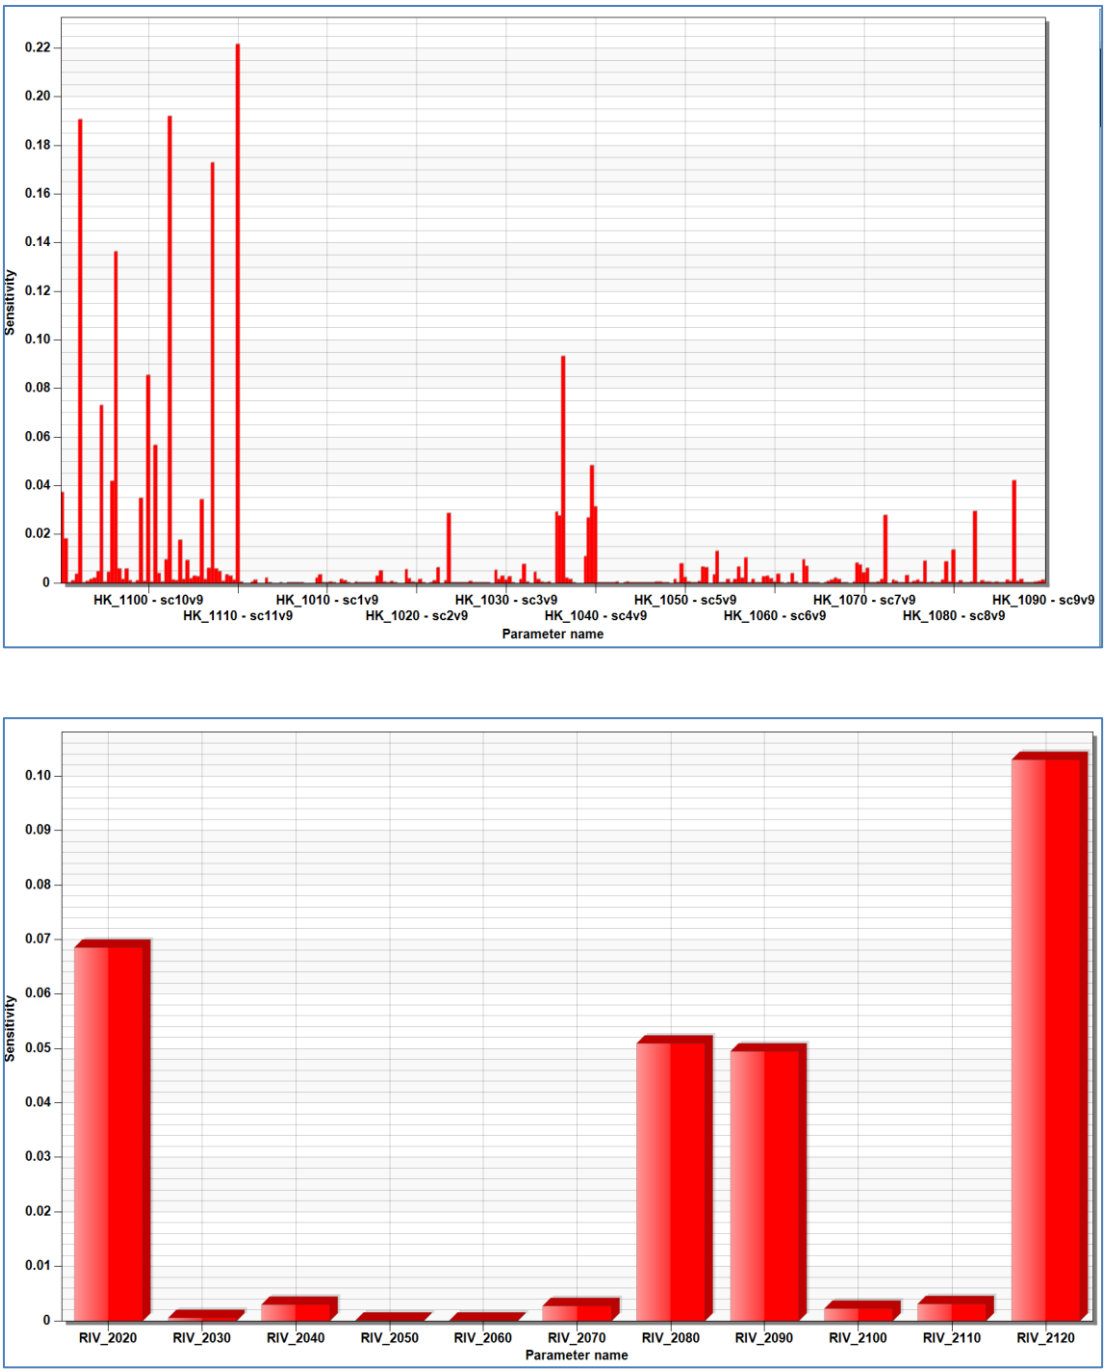

Figure 8-16. Sensitivity evaluation of hydraulic conductivity (top) and bed conductance (bottom) values obtained from automated parameter estimation assuming heterogeneity of geological strata.

8.11 Usability and confidence level

No model can be claimed to be a unique representation of the simulated object or subject or answer all possible questions on it. The steady-state models presented in this thesis are intended to represent long-term average conditions of the

groundwater flow system on a catchment-scale and, therefore, are not expected to be able to directly and precisely help with local-scale questions (e.g. effects of abstraction from a particular well on a nearby stream) or what would be the consequences of global sea level rise on the groundwater resource. The models presented here serve well their objectives, which are centred around characterising the LMC groundwater flow system and validating the presented catchment-scale conceptual model.

The Australian groundwater modelling guidelines provide a method to establish confidence level for groundwater models based on semi-quantitative assessment of the available data on which model is based, the manner in which the numerical model is implemented and calibrated, and how the predictions are formulated (Barnett *et al.*, 2012). The guidelines define three classes, 1-3, with Class 3 being the highest level of model confidence. The guidelines clarify key indicators and provide examples of model applications for each model confidence tier. The main features of the LMC groundwater flow models with regards to the Australian groundwater modelling guidelines confidence classification system are as follows:

1. Data

   - Rainfall and evaporation data are available (Class 3)
   - Reliable land-use and soil-mapping data available (Class 3, commensurate with the model scale)
   - Good quality and adequate spatial coverage of digital elevation model to define ground surface elevation (Class 3)
   - Groundwater head observations and bore logs are available but do not provide adequate coverage throughout the model domain (Class 2)
   - Streamflow data and baseflow estimates available at a few points (Class 2).

2. Calibration

   - Model is calibrated to heads and fluxes (Class 3, suitable for catchment-scale modelling)

- Acceptable calibration metrics (Class 2)
- Reasonable water budget figures (Class 2)
- Calibration statistics are generally reasonable (Class 2).

3. Temporal performance

- The LMC is not transient so measures relating to temporal performance do not apply in assessing its level of confidence class.

4. Prediction

- The LMC model has not been intended to be used in predictions, so this aspect is not relevant in determining its confidence level class.

5. Key indicators

- Key calibration statistics are acceptable and meet set targets (Class 3)
- Mass balance closure error is less than 0.5% of total (Class 3)
- Model parameters consistent with conceptualisation (Class 3)
- Appropriate computational methods used with appropriate spatial discretisation to model the problem (Class 3).

Accordingly, the LMC models can be designated Class 2 level of confidence, with many Class 3 level of confidence criteria met. The presented models are particularly useful as catchment management tools. They also provide reliable basis for subsequent higher confidence class models and provide basis for systematic data collection planning.

8.12 Uncertainty and limitations

The LMC groundwater flow models presented in this thesis are based on two other models, the soil moisture balance model presented in Sections 4.7 and the lithostratigraphical model presented in Section 8.3.3. Both models are uncertain and their uncertainties naturally transpire into the groundwater flow models that are

based on them. In particular, the SMB model used to calculate groundwater recharge sets that quantity at zero in urban and suburban areas (sections 4.7.1 and 4.7.3). Specialised investigations are needed to assess urban groundwater recharge in the LMC.

Assuming groundwater recharge to be zero in built-up areas is considered a limitation rather than an uncertainty in the models presented here. In general, across many studies throughout the world, urban recharge has been found to be greater than pre-urbanisation (e.g. Barrett *et al.*, 1997; Cook *et al.*, 2001; Foster *et al.*, 2005; Hughes & Mansour, 2005; Lerner, 2000, 2002). Nevertheless, there is very little research on the effects of urbanisation on groundwater recharge in New Zealand and it is regularly either trivialised or ignored altogether. For example, commenting on the estimation of groundwater recharge by Hadfield (2001), Toews and Moreau (2014) argue that groundwater recharge over the residential area of Matamata (c. 3.7 km²) is expected to be reduced due to runoff diversion to stormwater drainage from paved surfaces. Singh *et al.* (2018) contemplate that urban settlements and mountainous areas with steep slopes, hard rocks and thin soil layers have a low potential to contribute to groundwater recharge. There is a clear need for further study of urban groundwater recharge in New Zealand.

The LMC groundwater flow models are subject to uncertainties relating to the flow and head data used to the calibrate them and the use of average values to represent long-term steady-state conditions is also a source of uncertainty. Simplifying assumptions unavoidable in any modelling work also introduce uncertainty in the LMC groundwater flow models, e.g. the inclusion of anisotropy in bulk hydraulic property values. The lack of good data on groundwater abstraction and screens for both production and monitoring wells contributes to the models' uncertainty.

The discussion of parameter sensitivities in Sections 8.10.2 and 8.10.3 provides a general feel of the models' level of uncertainty. The general agreement between the initial manually calibrated model and the homogeneous and heterogeneous automated calibrations of the model provide a reasonably good level of certainty in

the correctness of the conceptual model and the appropriateness of the numerical model implementations, particularly with regards to the stipulated boundary conditions. During the modelling exercise, the model sensitivity for the location of the no-flow boundary that coincide with the assumed surface water divide in the area between Sanson and the coastline has been anecdotally assessed, but neither quantified nor documented. The current location of the no-flow has been considered more appropriate that the groundwater divide in the same area assumed by Zarour (2008). In the models presented here, an 'unnamed' catchment has been removed from the model domain and considered to be part of the Rangitikei system rather than the LMC system. This assumption has been reached after examining the perceived groundwater flow paths in the area from different model setups.

It must be noted that any more advanced modelling will be subject to a higher level of uncertainty. For example, storativity is not used in the LMC model because they are steady-state simulations. Transient simulations require this parameter and will be affected by the uncertainty associated with it. Particle tracking, transient, solute transport and smaller scale models will all be subject to further sources of uncertainty.

8.13 Key findings

The numerical models presented in this thesis indicate that groundwater flow in the LMC is generally from the northeast to the southwest, largely aligned to geological structure and rivers (Figure 8-17). The sedimentary stratigraphical sequence is hydraulically continued without distinct aquifers and aquitards. Explicitly, this means that sandy material in the LMC are an integral part of the aquifer system and should not be discarded in any analysis. It may be convenient to screen wells in gravelly sections where higher yields are expected, but the groundwater taken from wells come from storage and movement throughout the entire aquifer system.

The models indicate that the hydraulic conductivity of the aquifer material ranges between less than 0.01 m/d and c. 120 m/d. the aquifer and rivers are highly

hydraulically connected, with the rivers mainly gaining from groundwater (Figure 8-17). There are places with prominent upwards hydraulic gradients which give rise to strong artesian head in their wells, e.g. the Manawatu Golf Course area (Figure 8-18).

Although calibrated using different methods, similar results have been obtained from the manually and automatically calibrated models that assume geological material homogeneity and the automatedly calibrated model that assumes geological material heterogeneously. In all three models, computed heads in the higher parts of the catchment are higher than the observed heads, and vice versa in the lower catchment. This may be due to underestimating the hydraulic conductivity of the Castlecliffian and older strata (> OIS 10) that prevail in the upper part of the catchment, or overestimating groundwater recharge in that area. However, it has not been possible to obtain better calibration of the models using lower hydraulic conductivity values and recharge values obtained from soil moisture modelling have not been altered during the calibration of the three models. This pattern of calculated-observed values relationship could also be related to the above-average rainfall noticed over the period 1985-1995 (Section 4.6.2). The current stead-state models cannot account for such a change, which may have happened at varying rates across the catchment.

The noticeable agreement between manual and automated model calibrations assuming aquifer material homogeneity and heterogeneity supports the opinion of Ye *et al.* (2010) noted in Section 3.2 that overall model uncertainty is greatly more susceptible to conceptual uncertainty rather than parametric uncertainty.

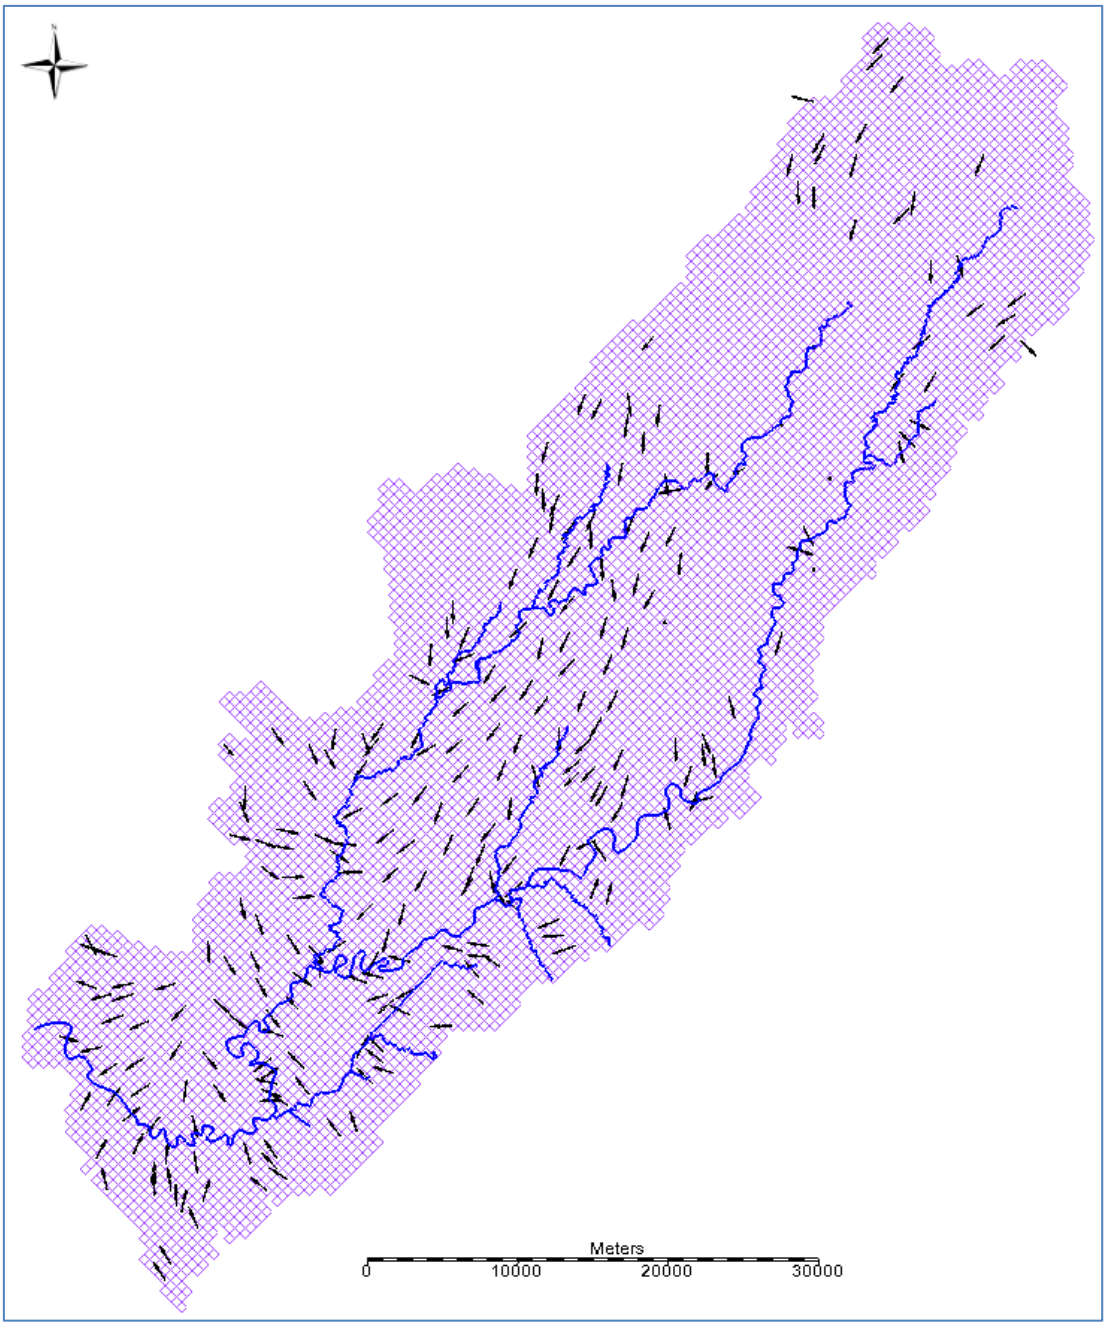

Figure 8-17. Flow velocity vectors showing groundwater flowing mainly towards rivers in Layer 1 of the LMC model.

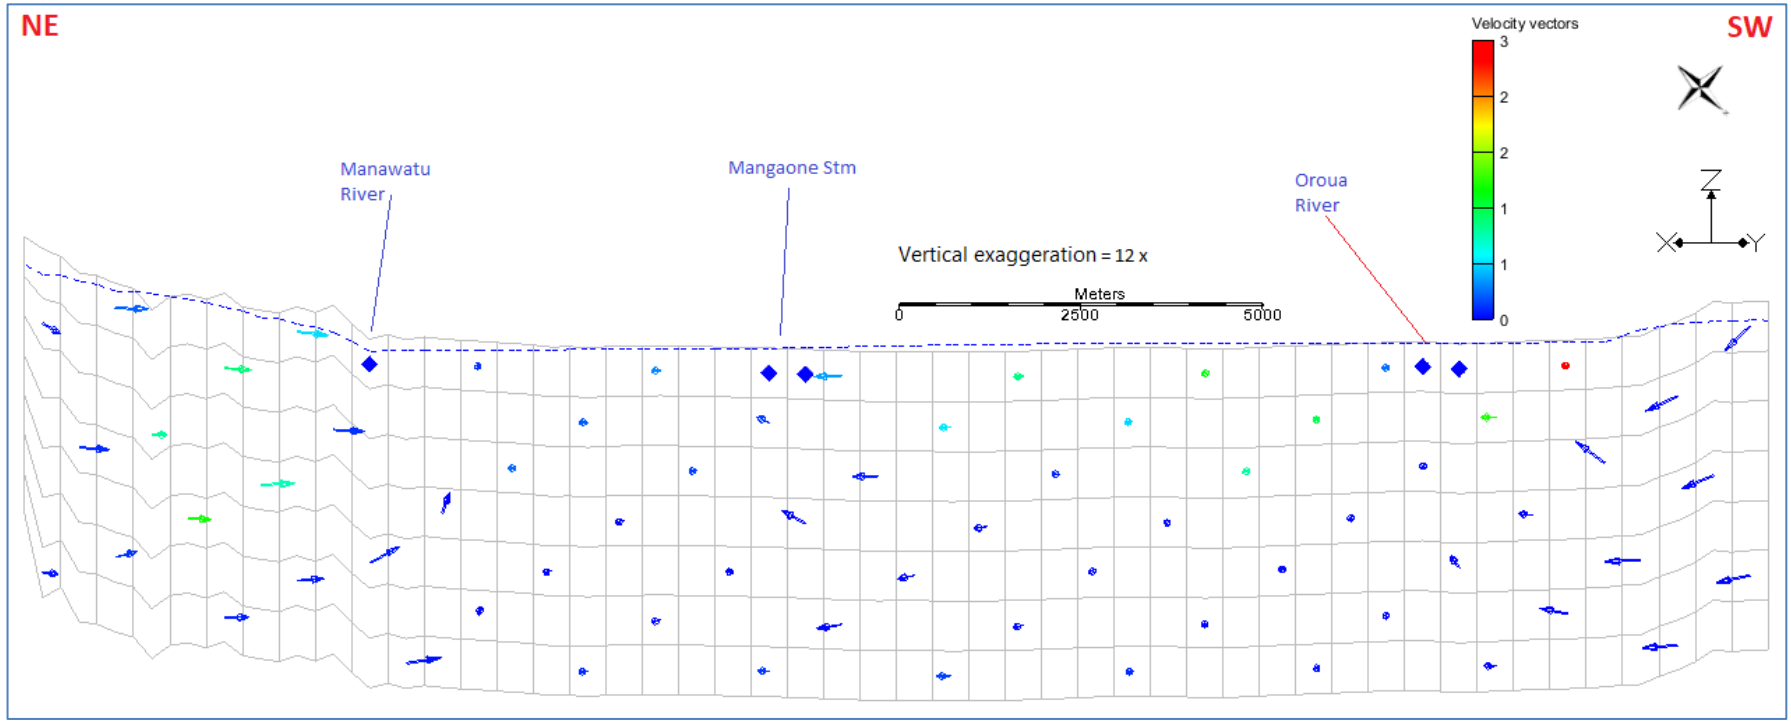

Figure 8-18. Cross-section through the Square at the centre of Palmerston North, showing vertical groundwater flow components.

The LMC models suggest that groundwater abstraction in the catchment has been generally within sustainable limits. Table 8-11 shows that groundwater abstraction may have been reducing overall flow in rivers by around 5%. However, the models' scales and levels of calibration do not allow making any assessments of the effects of certain abstractions on particular rivers or streams and being steady-state, the LMC models cannot be used in making seasonal assessments or predictions of surface water depletion due to groundwater abstraction.

Table 8-11. Heterogeneous hydrolithostratigraphical units model calculations of overall average effects of groundwater abstraction on main river flows and other elements of the water budget.

Water budget component	Groundwater abstraction scenario			
	None	Permitted wells only	Consented Wells only	All wells

Chapter 9 Conclusion and recommendations

9.1 Introduction

Groundwater in the LMC is an important resource for sustaining human and animal life and for the social, economic and environmental wellbeing of the catchment and its communities. Reliable, relevant, realistic and useful understanding of the hydrogeology is fundamental for managing the resource beneficially and sustainably.

Numerical modelling provides an integrated analytical framework to develop a robust understanding of groundwater resources and is a useful tool that can help with resource planning and management through allowing the exploration, testing and comparison of alternatives. This thesis updates knowledge of the LMC hydrogeological system and presents defendable conceptual and numerical models developed to represent it. The information and tools presented herein can enhance the ways by which stakeholders in the catchment communicate, collaborate, develop policies, prepare plans and make decisions regarding the protection and sustainable management of land and water resources and the larger environment. The approach followed in this research and the developed new modelling techniques can be adopted to other areas in New Zealand and internationally, particularly to simulate stratified heterogeneous aquifer systems.

9.2 The modelling process and techniques

Development of the LMC groundwater conceptual model was achieved through the synthesis of a huge amount of data on the geology, soil, climate, surface water, land use, land cover, and information sourced from boreholes about the tapped lithology, groundwater level, quality and abstraction. Numerical model implementation was obstructed by the lack of important information such as groundwater recharge estimates and the maldistribution of some data, particularly

and arguably most importantly lithological well logs. Incorporating heterogeneity in the numerical groundwater flow model was deemed necessary to enhance the model representativeness of the simulated system.

To understand the influence of geomorphology on the groundwater system, topographical data were analysed and a landform model was specially developed. Geomorphological investigation indicates that the groundwater system is largely controlled by gravity, including the co-existence of various scale (local, intermediate and regional) flow systems.

A soil moisture balance modelling code was developed to provide the required groundwater recharge estimates for general water balance calculations and numerical groundwater flow modelling purposes. The developed SMB model is based on the United Nations Food and Agriculture (FAO) Penman-Monteith equation (Allen *et al.*, 1998) and compensates for the lack of readily useable soil data by transforming available New Zealand Fundamental Soil Layer (FSL) data into a United States Department of Agriculture (USDA) Soil Texture Classification (STC) proxy classification. Lack of climate data was overcome through the utilisation of virtual climate stations (VCS) data obtained from NIWA. The developed SMB model accounts for the depletion of evapotranspiration below the stress point as prescribed in the FAO Irrigation and Drainage Paper 56 (Allen *et al.*, 1998), providing a more realistic representation of the soil moisture fate than models that do not account for this phenomenon. The developed SMB model provides a simple but yet an effective tool to evaluate actual evapotranspiration for various purposes including crop water demand assessment, surface runoff for catchment yield studies, and groundwater recharge for hydrogeological investigations and modelling. The produced SMB modelling utility can be easily accustomed to other locations in New Zealand and internationally. It has been satisfactorily used to assess groundwater recharge in Nelson (Zarour *et al.*, 2017). The model code could be enhanced by adding contaminant load calculation capabilities, e.g. to assess nutrient loads and concentrations from various historical and planned land

use scenarios. It can also be enhanced by adding components to represent urban hydrology elements, preferential, lateral and intercepted soil water flow.

The groundwater flow model configuration, parametrisation, boundary and initial conditions were set up on geological and hydrogeological basis. Developing an appropriate geological model on which the numerical groundwater flow model can be based was complicated by the quality of the well drilling cuttings lithological descriptions and inadequate spatial coverage of this dataset. Based on the developed understanding of the geological history and depositional environments for different lithostratigraphical units, a systematic approach was devised to define stratigraphical unit contacts at wells. To enable lithostratigraphical correlation and extrapolation across the catchment in areas and at depths that have no or inadequate well log coverage, a method was developed to represent the geology in such areas by imaginary wells and cross-sections. By supplementing real surface and subsurface geological data with virtual geological data, it was possible to build a realistic 3D geological model for the catchment that was used in the groundwater flow models. The produced model correctly predicts marine incursion in interglacial periods (MOI 5, 7, and 9) and the extent of fluvial aggradation (mostly gravels) in glacial periods (MOI 2-4, 6, 8, and 10). It also predicts that alluvial deposition becomes progressively confined inland by uplift and growing geological structures (anticlines) and faults as theorised by Begg *et al.* (2005). A multitude of additional data types can be incorporated into the developed geological modelling approach including surface and subsurface geophysical data, structural geology measurements and remote sensing. The new geological modelling technique has global applications and can facilitate the construction of geological models for various purposes, especially in New Zealand where Quaternary age sediments are particularly important.

To enhance the preventiveness of the main characteristics of the LMC aquifer system, it was deemed necessary to incorporate geological stratification and material heterogeneity in the numerical groundwater flow models. Zonal and pilot point numerical model parameterisation and automated calibration techniques were

hybridised to represent hydraulically heterogeneous strata. The new zoned pilot points technique can be used universally to more realistically simulate stratified heterogeneous aquifer systems, enhancing model representativeness and, subsequently, confidence and acceptability levels.

9.3 Main results

The work undertaken produced a comprehensive defensible conceptual model of the LMC hydrogeological system with in-depth analysis of various relevant components like the geology, climate, interconnectedness with surface water, the main characteristics of the groundwater flow system and groundwater quality. A soil moisture balance modelling tool has been developed and used in a water balance context to establish and evaluate the relationships between rainfall, surface runoff, groundwater recharge and groundwater-surface water interaction. The developed soil moisture balance modelling utility can be used in the LMC for surface water and groundwater resources and irrigation management and can be adopted elsewhere in New Zealand and globally.

This research produced the first realistic stratigraphical model for the LMC. The stratigraphical modelling strategy developed in this research through the utilisation of imaginary wells can be further enhanced and the stratigraphical model presented can be refined to help with other geological research, particularly stratigraphy and structural geology.

The data generated from analytical calculations and the newly achieved understanding of the hydrogeological system have been incorporated in a numerical model for the area that confirms the aptness of the work and its findings. A novel approach has been developed and applied to account for heterogeneity in the stratigraphical sequence through pilot point interpolation in each stratigraphical unit. Overlaying the stratigraphical units on the groundwater flow model finite difference grid enabled realistic representation of the groundwater system and its general characteristics and behaviour. The presented numerical groundwater flow model can be maintained by stakeholders like Horizons Regional Council as a tool

to help them in their statutory functions. The systematic stratigraphical and numerical groundwater flow modelling approaches can be copied elsewhere in New Zealand and universally.

This research has proven that the groundwater resource in the LMC is best represented by a continuous flow system rather than a set of distinct aquifers and aquitards. The importance of the fine-grained, interglacial times deposits in the stratigraphical sequence is evident and these strata cannot be overlooked in hydrogeological assessments by considering them aquitards. Successful manual and automated calibration of the numerical models presented in this work gives confidence in the validity of the proposed conceptual model and its components, including stratigraphical characterisation, aquifer properties and groundwater-surface water interaction.

It is acknowledged that the calibration residuals from the numerical models are not very small. Nevertheless, they are totally suitable for the objectives, scale and resolution of the developed models and commensurate with the quality of the available data. In all cases, this model and in fact all other possible models should never be considered as the only representation of reality. They are useful tools, but not exclusive representations of real-world systems.

Overall, it seems that anthropogenic influence over the LMC groundwater system has been limited. Groundwater quality has not changed much since monitoring started about 50 years ago or perhaps even since the first hydrogeological study was undertaken in the catchment about 120 years ago.

9.4 Further work

This thesis represents a one stop shop for information on groundwater in the LMC. The knowledge generated through the completed research and the presented conceptual and numerical models provide solid basis for further geological and hydrological work in the catchment. The developed techniques for modelling soil moisture, aquifer system stratification and heterogeneity can be applied in other

areas in New Zealand and internationally and can be further enhanced to provide more advanced modelling capabilities. The following actions and further research are recommended to capitalise on the findings of this research and maximise benefits from it to the studied catchment, other areas in New Zealand and hydrogeological research in general.

(1) Water resource planning and management

- Utilisation of the findings of this research and the developed conceptual and numerical groundwater flow models to meet National Policy Statement for Freshwater Management (NPSFM) requirements including the definition of freshwater management units and enforceable surface water and groundwater quality and quantity limits based on best available information and scientific and socio-economic knowledge as described by Gaz (2017).
- Adopting the developed groundwater flow models as formal tools to estimate the consequences of alternative water and land use scenarios to help with resource planning and management efforts. This can include deciding on resource consent applications for groundwater takes in which the developed models can be used to assess effects on the environment and other users of the resource.
- Utilising the developed SMB model to estimate actual evapotranspiration, irrigation demand, surface runoff and groundwater recharge and surface water catchment yield across all freshwater management units in the Manawatu-Wanganui region to help with regulatory and operational decision-making by the council and land and water resources users (e.g. irrigators, interest groups). Assessment of groundwater recharge in all groundwater management zones in the Manawatu-Wanganui region is particularly important because the NPSFM requires regional councils to set enforceable quality and quantity limits for surface water and groundwater based on best available information and scientific and socio-economic knowledge (Gaz, 2017).

(2) Hydrological monitoring, databasing and investigations

- Initiation of a comprehensive review of the regional land and water resources data gathering networks and programmes, purposefully targeting the collection of data for the development of useful surface water and groundwater quantity and quality models that can be used to meet SoE responsibilities and help with resource management duties. The review can be LMC-specific or Manawatu-Wanganui region-wide.
- Embark on a programme of concurrent surface water gauging to enable better conceptualisation, quantification and numerical modelling of surface water-groundwater interaction in the LMC and the Horizons region.
- Commission water level measurement and hydrochemical sampling programme aimed at mapping the groundwater-seawater interface in the coastal area. The collected data will enable better design of the seawater intrusion monitoring network and enhance groundwater modelling resources.
- Collaborate with drillers, universities, Crown Research Institutions, consulting firms and professional syndicates like the New Zealand Hydrological Society and Geoscience Society of New Zealand to enhance and standardise lithological borehole sampling and cutting description skills to enable efficient lithostratigraphical interpretation and modelling.
- Review database lithological records, correct typographical errors and standardise terminology to enable computerised processing of the data.
- Launch an environmental isotope programme to collect groundwater recharge source and age determination data.
- Review and update groundwater and related environmental databasing systems to make sure data are readily available for research and studies.
- Enhance metadata collection and documentation to support future research, e.g. field sampling and laboratory analysis methods for groundwater quality data.
- Lobbying for the completion of S-map for the LMC to provide better soil data for soil moisture modelling and other purposes.

- Develop and implement a plan to streamline and enhance lithological description capabilities in regional and national well drilling service providers to enable effective geological and hydrogeological modelling.
- Arranging professional lithological logging for deep wells that will be drilled in the catchment to provide high quality, high resolution data to refine geological models. This will require collaborating with drillers and well owners and may involve lithological description of samples by qualified geologists, grain-size testing, microfossil analysis, geochemical analysis of sediment and water samples.
- Install strategically-positioned multilevel groundwater level and quality monitoring setups to gather data on vertical changes in groundwater to enable reliable assessment of the impacts of land and water use practices and help with future modelling.
- Update surface water flow statistics undertaken by Henderson and Diettrich (2007). This is particularly relevant because there were no long data records at the time of the original study and there has been an extreme even of low rainfall in 2014 as revealed in Section 4.6.2.
- Update the rainfall maps and statistical analyses by Tait and Sturman (2008) and attempt making future predictions for rainfall in the LMC and wider region. This is particularly important following the extreme even of low rainfall in 2014 presented in Section 4.6.2.
- Launch a programme to enhance borehole data availability through surveying locations and elevations, measuring depth to water and obtain missing well construction detail (screen and open intervals) using downhole cameras.
- Pull out pumping test data from various digital and paper sources and organise them in a serviceable database to help with environmental effect assessments and future groundwater investigations and modelling.
- Organise a programme of well designed, performed and analysed step-drawdown and constant discharge rate pumping tests followed by adequate groundwater level recovery monitoring at strategically selected locations to

obtain better data on aquifer hydraulic conditions (confinement and boundary conditions) and properties (transmissivity, storativity and leakage). The data will be useful to assessment of environmental effects of various activities and will provide much needed data for hydrogeological modelling. This programme can be also used to educate drillers and consultants on best practices in well performance and aquifer tests.

- Commissioning stratigraphical, structural geology, geophysical and remote sensing investigations to provide additional data for geological models that can be used for various environmental resource and natural hazard management purposes.
- Update the spatial and temporal variations and trends in groundwater quality assessment undertaken by Daughney *et al.* (2009), including using different analytical techniques.
- Commission an investigation on the effect of organic material in the geological sequence (normally reported as peat in drillers' lithological descriptions) on nitrate attenuation capacity. This aspect may have important resource management policy implications. This investigation must comprise sampling and chemical analysis of water and geological material, field experimentation and simulation (particle tracking, contaminant transport and/or thermodynamics modelling).
- Commission a project to understand the effects of urbanisation on groundwater recharge, including modification of the characteristics of the land surface and losses from water and wastewater storage and distribution systems.

(3) Modelling

- Verifying the LMC SMB model to determine its conceptual and parametric sensitivity, uncertainty, confidence levels and usability in resource and environmental management.

- Develop a methodology to calibrate the developed SMB model using surface water, soil moisture and groundwater recharge observations, which may be particularly useful to estimate catchment yield and help in flood-forecasting.
- Improving the LMC SMB model code through the addition of preferential, lateral and intercepted flow options to enable more complete and more realistic representation of the soil zone hydrology in any modelled system across in the country and the world.
- Adding contaminant load calculation capabilities to the developed SMB model to help with land use management efforts in New Zealand and internationally.
- Extending SMB modelling to the rest of the Manawatu-Wanganui region to help with natural resource and environmental hazard planning and management.
- Refining the LMC geological model by incorporating all lithological well logs not included in the model presented in this thesis to enhance its quality and representativeness of the LMC geological model and make it more useful for resource management, environmental hazard planning and response (e.g. flood protection and liquefaction studies), locating water wells and determining their depths, and civil engineering projects.
- Investigating the adequacy of available data for geological modelling in other groundwater management zones in the Manawatu-Wanganui region, and where feasible, constructing geological models for hydrogeological and other environmental and natural resources modelling and research purposes.
- Upgrade the LMC finite difference MODFLOW groundwater flow models to the latest version of the USGS MODFLOW-USG modelling code to enable greater flexibility in the representation of geological and hydrogeological traits and enhance its overall ability to simulate land and water management scenarios.

- Converting the steady-state groundwater flow models presented in this thesis to pseudo-steady-state models to estimate aquifer storativity (S_y and S_s) and assess the models' sensitivity to these parameters.
- Using the presented models to provide regional-scale boundary and initial conditions in future finer-scale and/or transient groundwater flow and contaminant transport models, including delineation of capture zones through particle tracking or other techniques.
- Assessing the uncertainty in the presented models in relation to the location of the assumed no-flow boundaries to validate the extents of the LMC, Rangitikei and Horowhenua groundwater management zones. The NPSFM requires regional councils to define freshwater management units (Gaz, 2017).
- Developing the stratified heterogeneous steady-state groundwater flow model into a calibrated and verified transient model to explore the effect of the noticed change in rainfall pattern on the groundwater resource in the LMC and make predictions in respect to various possible natural and anthropogenic changes that can affect the groundwater and surface water resources quantity and quality in the LMC.
- Verifying and updating the models presented in this thesis in five years' time using new data to account for natural and anthropogenic changes (e.g. climate, land use, etc.).

Figure B-10. Yearly and monthly total and average flow calculated for Manawatu River at Palmerston North Teachers College (Site R10 in the map in Figure 5-5).

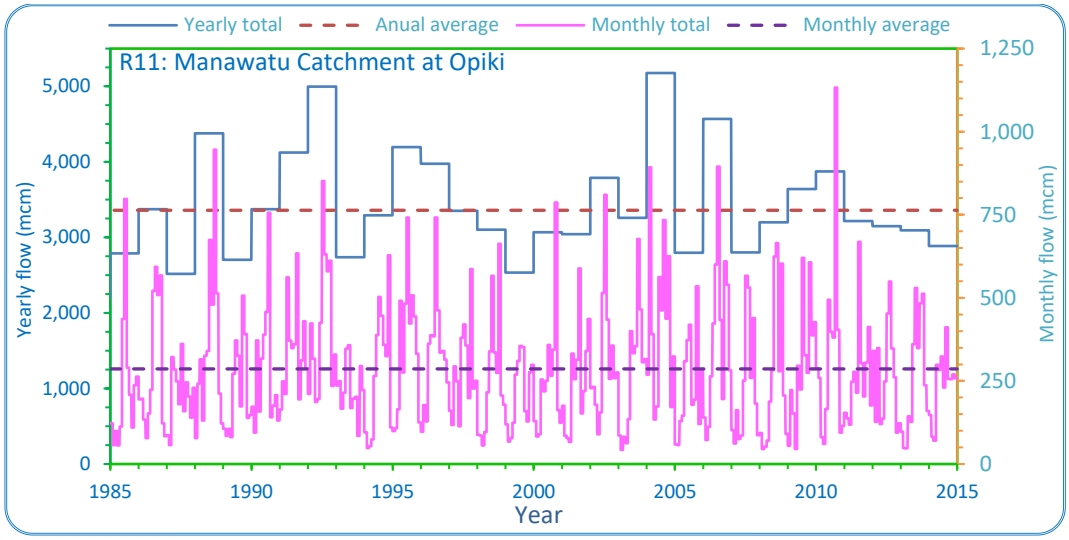

Figure B-11. Yearly and monthly total and average flow calculated for Manawatu River at Opiki (Site R11 in the map in Figure 5-5).

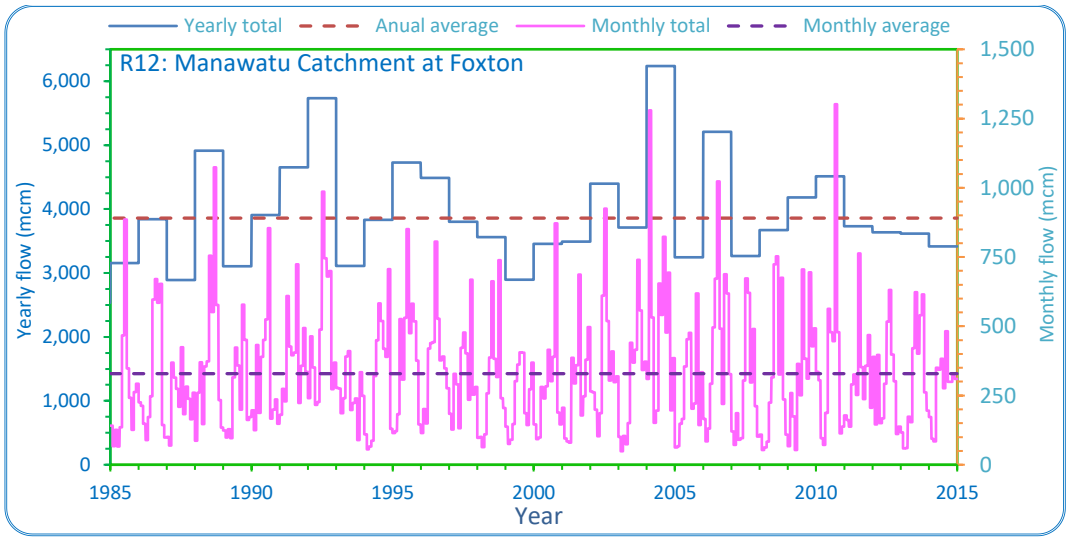

Figure B-12. Yearly and monthly total and average flow calculated for Manawatu River at Foxton (Site R12 in the map in Figure 5-5).

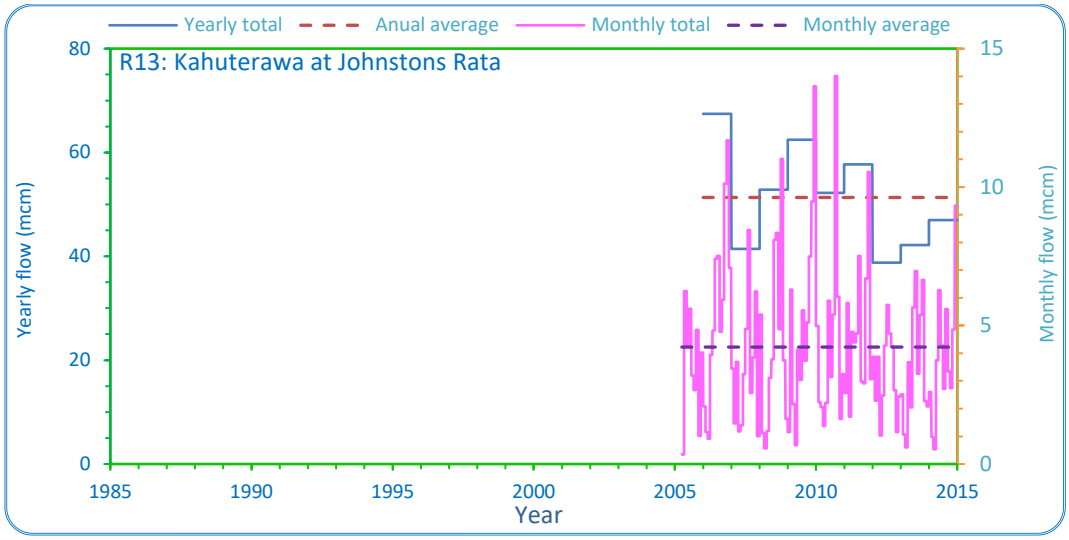

Figure B-13. Yearly and monthly total and average flow calculated for Kahuterawa Stream at Johnstons Rata (Site R13 in the map in Figure 5-5).

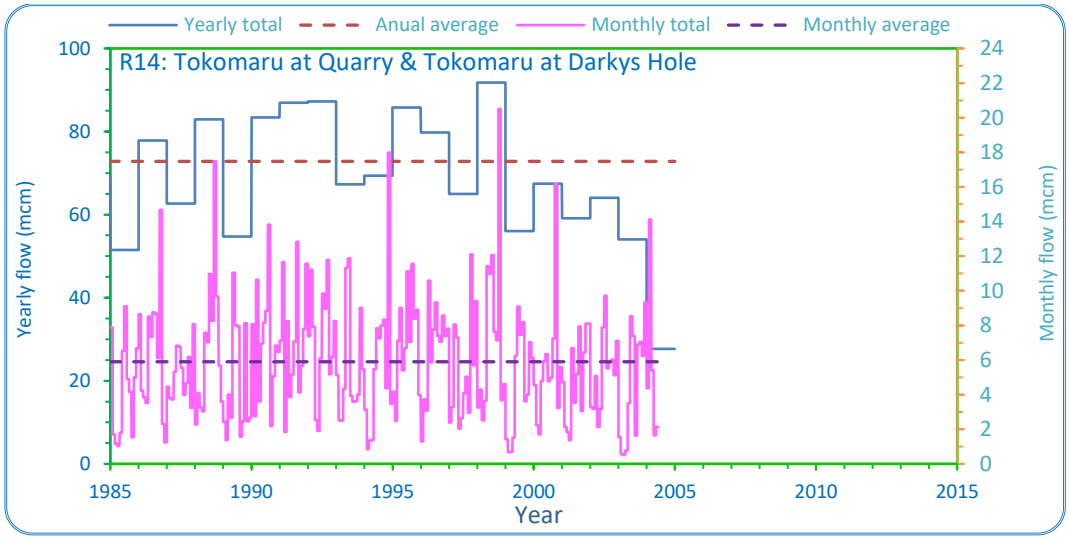

Figure B-14. Yearly and monthly total and average flow calculated for Tokomaru at Quarry and Tokomaru at Darkys Hole (Site R14 in the map in Figure 5-5).

Appendix C Groundwater level data and hydrographs

Table C-1. Summary of groundwater level monitoring records[70] in the LMC.

Figure number	Well ID	NZMG position			Measurement point		Well depth (m)	Screen position (masl)			Examined record length		Number of Readings	Groundwater level (masl)				GWL STDEV (m)
		Easting	Northing	Info source	Level (masl)	Info source		Top	Middle	Bottom	From	To		Min	Max	Mean	Median

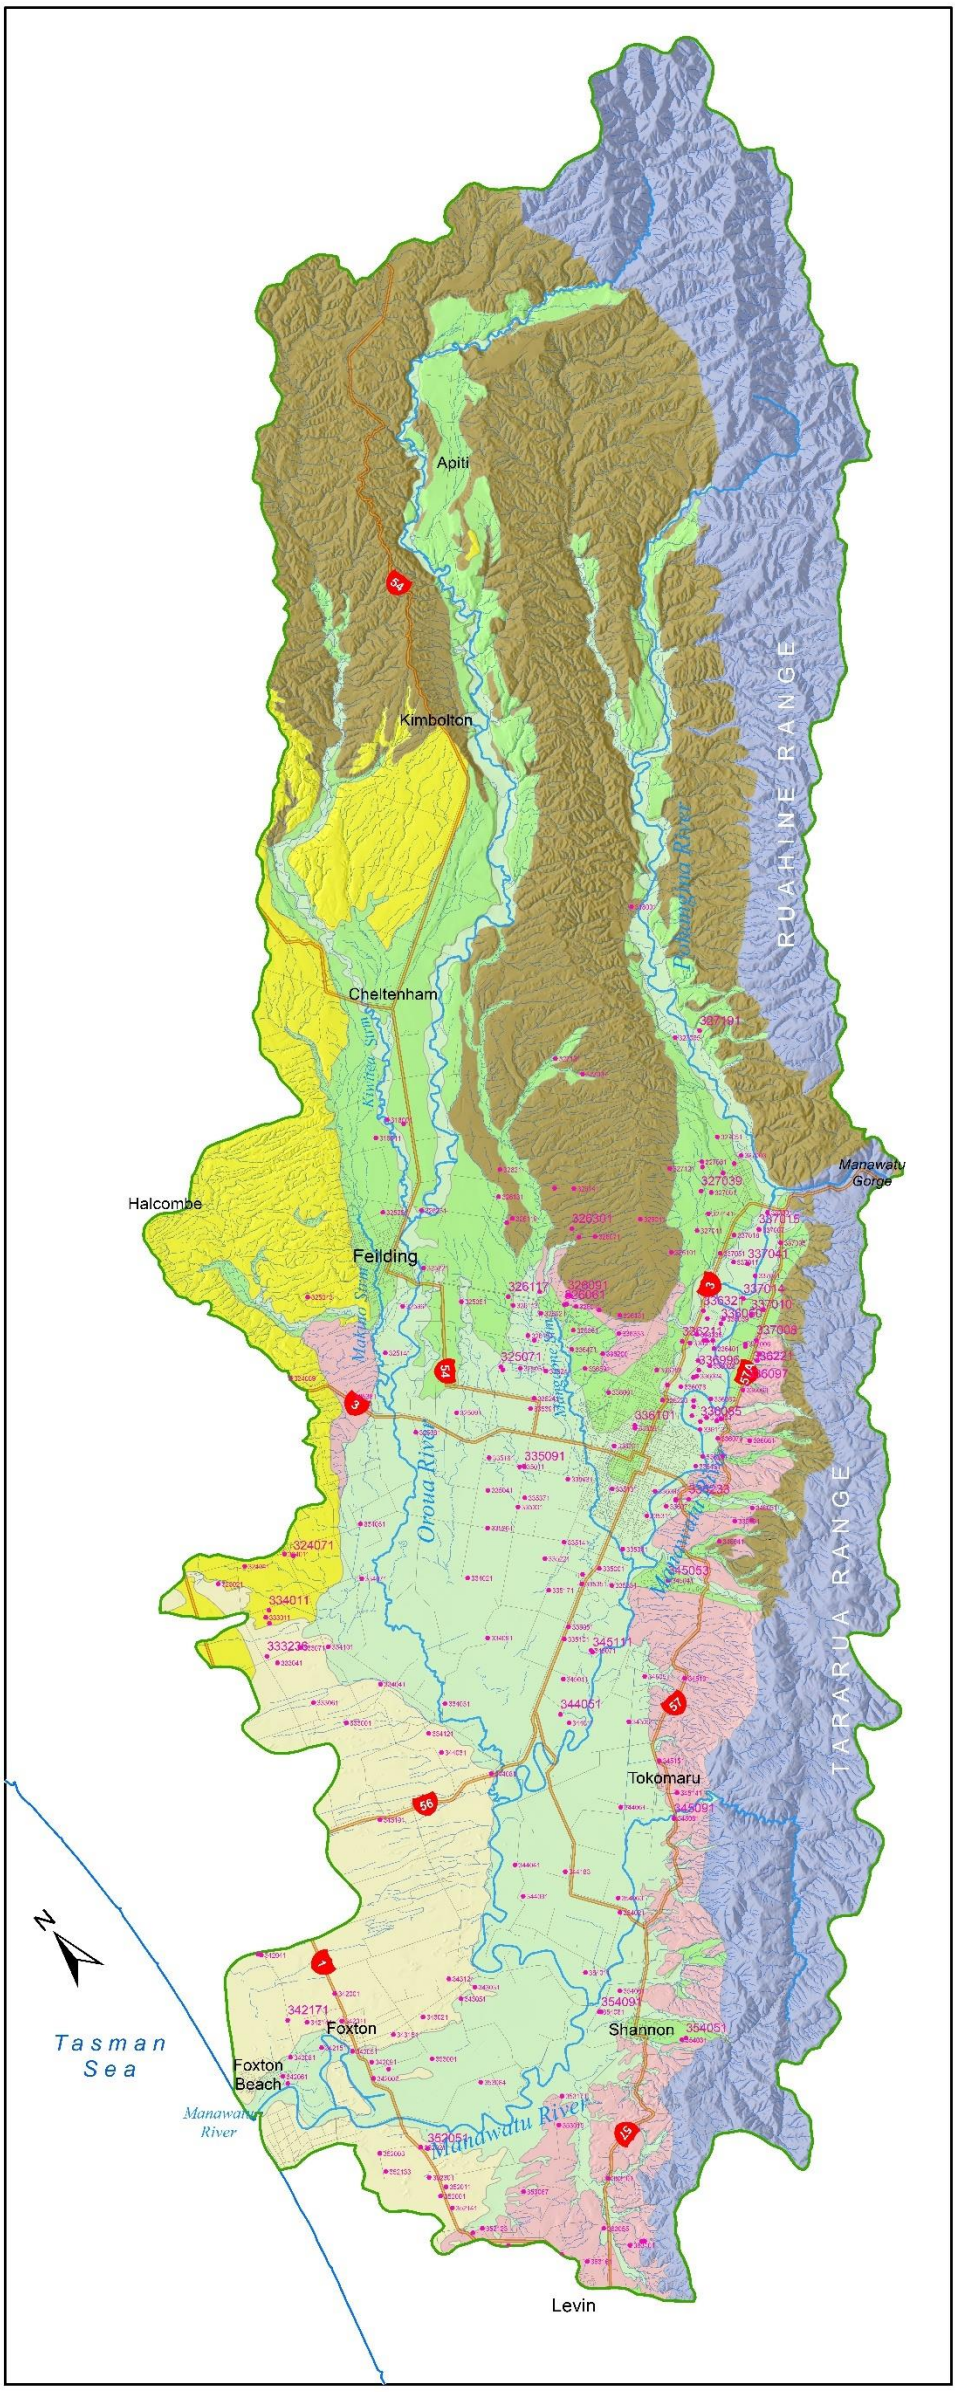
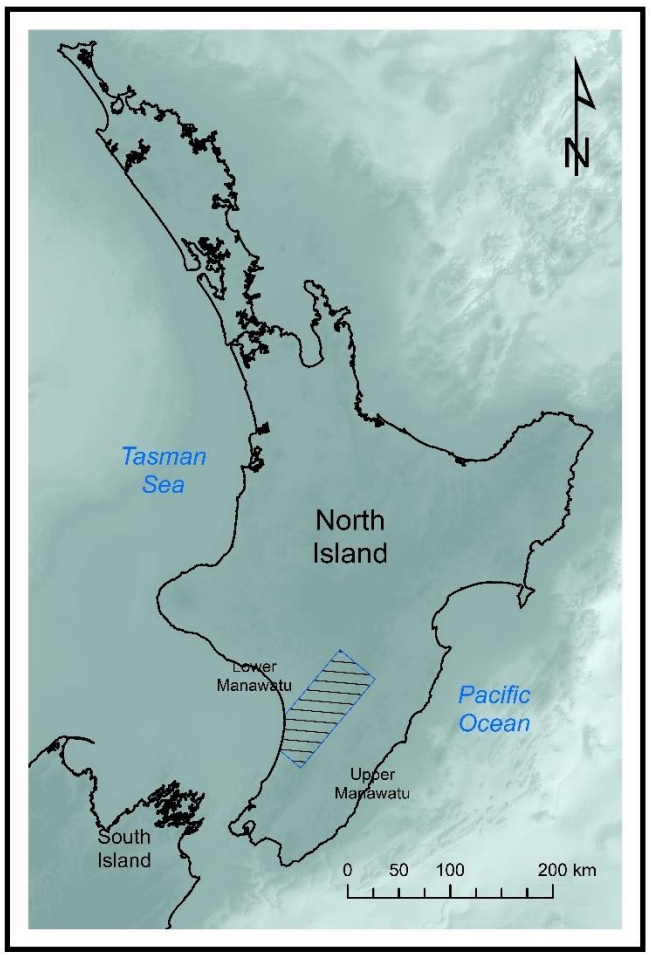
Appendix D Groundwater quality data





LOWER MANAWATU CATCHMENT SAMPLED WELLS

Legend

- Catchment boundary
- Coastline
- River
- Groundwater quality sampled well
- Stream/creek
- Highway
- Road

Simplified geology

Holocene

- Holocene alluvium
- Holocene sand dunes

Middle-Late Pleistocene

- Late Pleistocene alluvium
- Last Interglacial Marine Deposits
- Middle Pleistocene Strata

Plio-Pleistocene

- Plio-Pleistocene marine rocks

Permian-Late Jurassic

- Greywacke basement rock

0 2.5 5 10 15 20 km

Figure D-1: Map showing locations of groundwater quality samples listed in Chapter 7 and Appendix D.

Table D-1: Wells with complete, acceptable groundwater quality records in the Lower Manawatu Catchment and summary of data availability until the end of 2007.

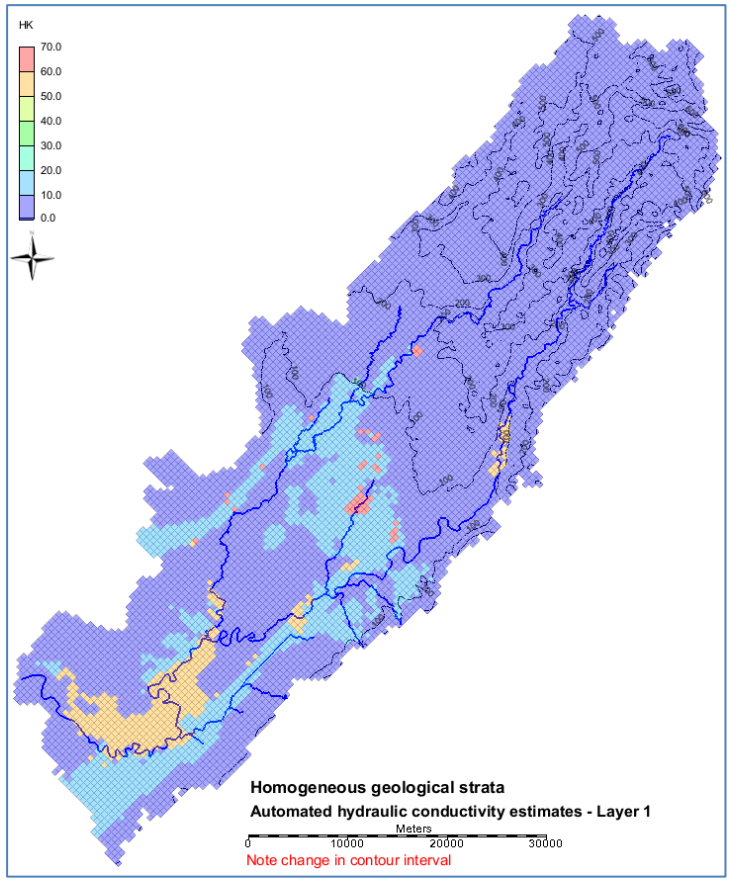
Figure E-1. Scatter plot of measured heads against model calculated heads from automated estimation of hydraulic conductivity assuming homogeneous geological strata and river/stream bed conductance values from Figure 8-9. The brown solid line represents the data linear trend, the red dashed line represents 10 m model overestimation, and the blue dashed line represents 10 m model underestimation. The trend line equation and linear regression goodness-of-fit (R^2) are shown on the graph.



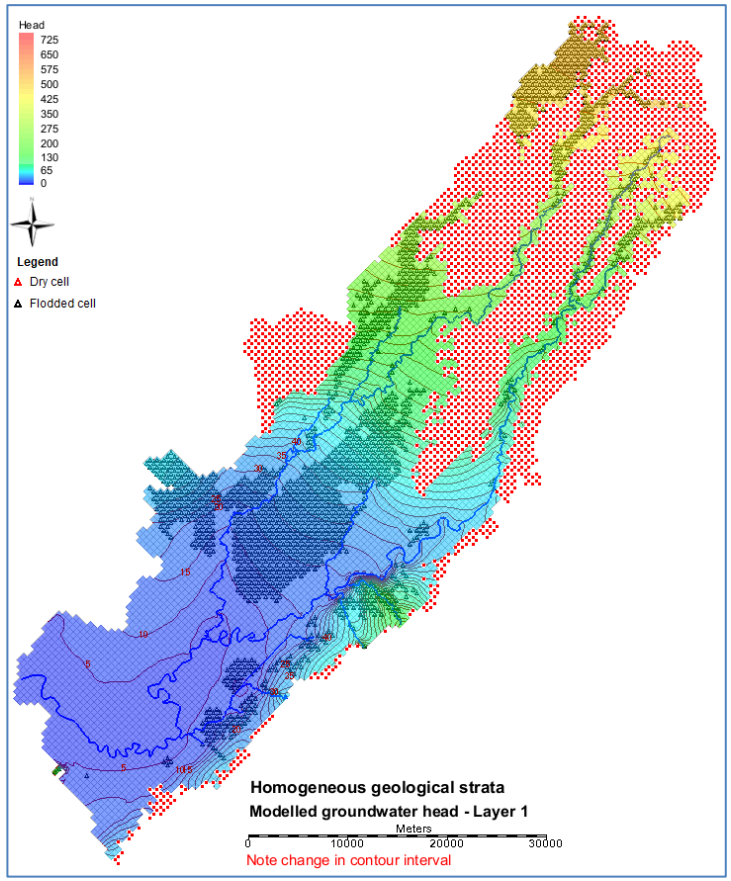


Figure E-2. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 1 assuming homogeneity of geological strata.

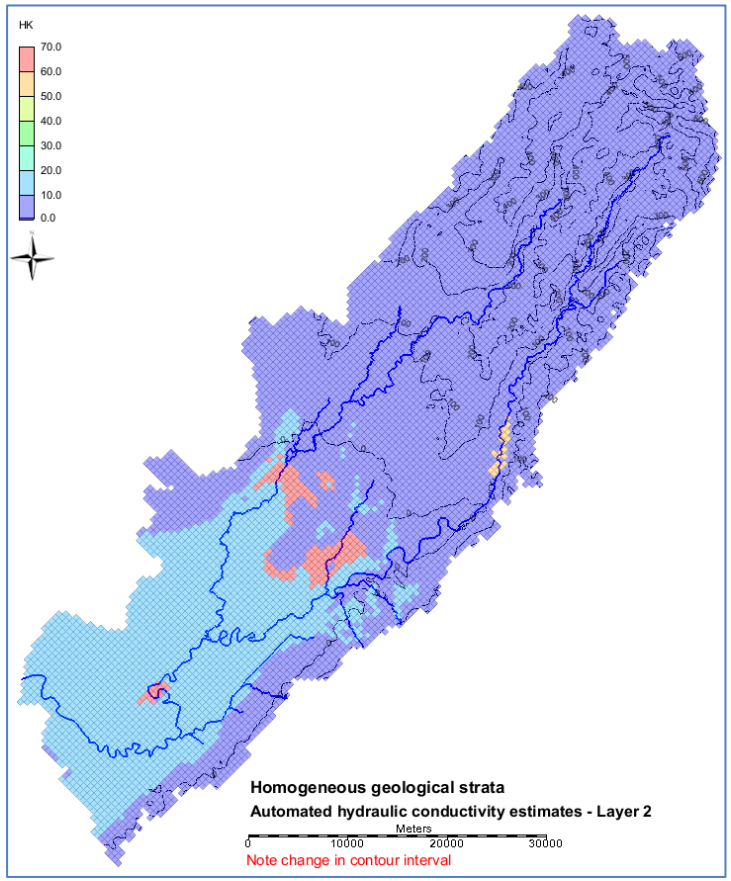

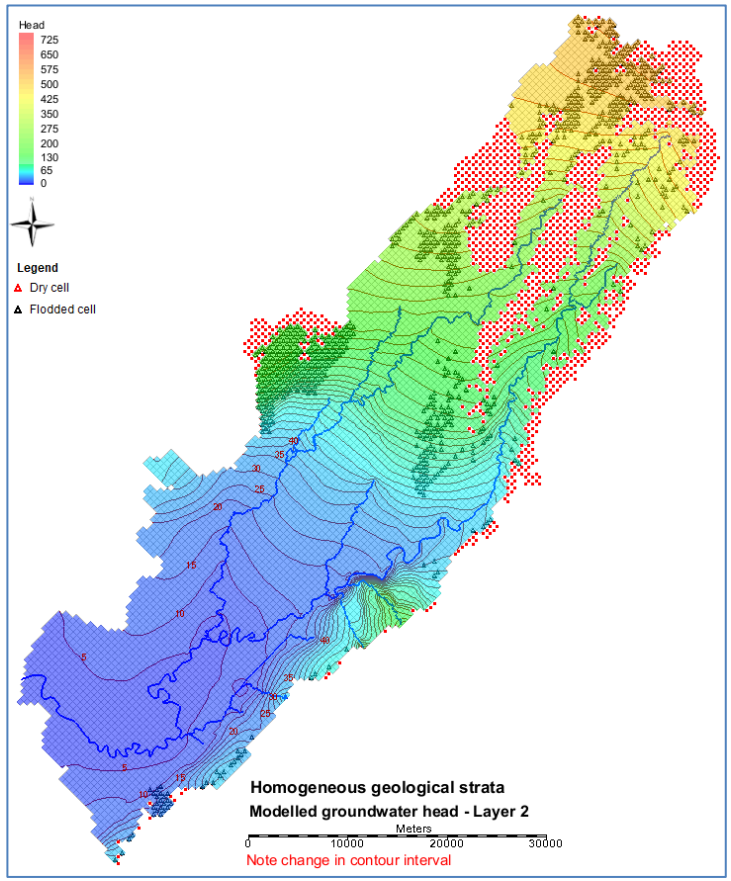

Figure E-3. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 2 assuming homogeneity of geological strata.

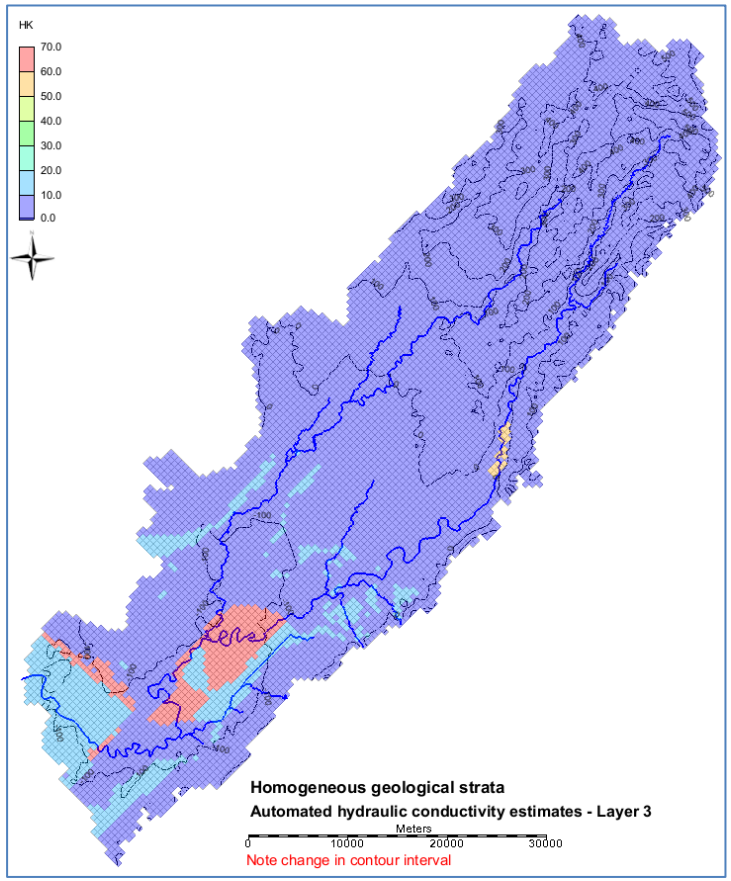

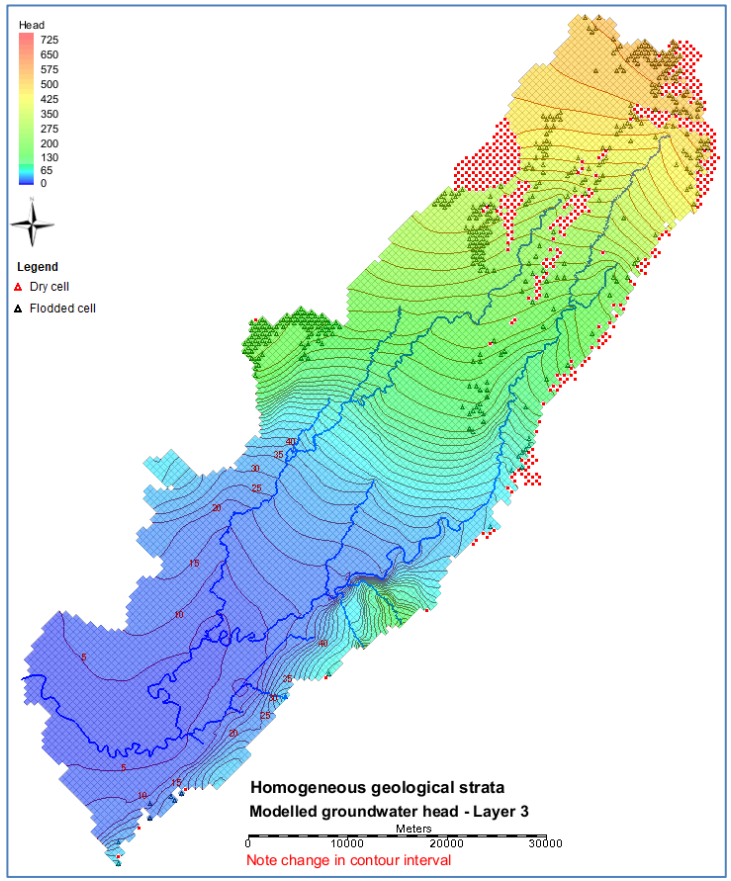

Figure E-4. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 3 assuming homogeneity of geological strata.

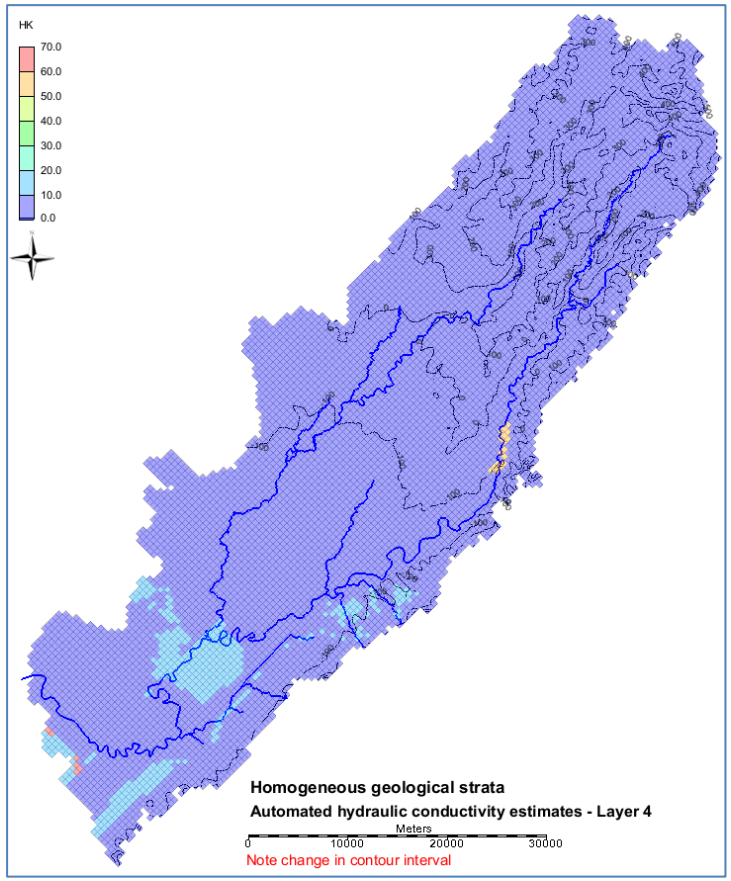

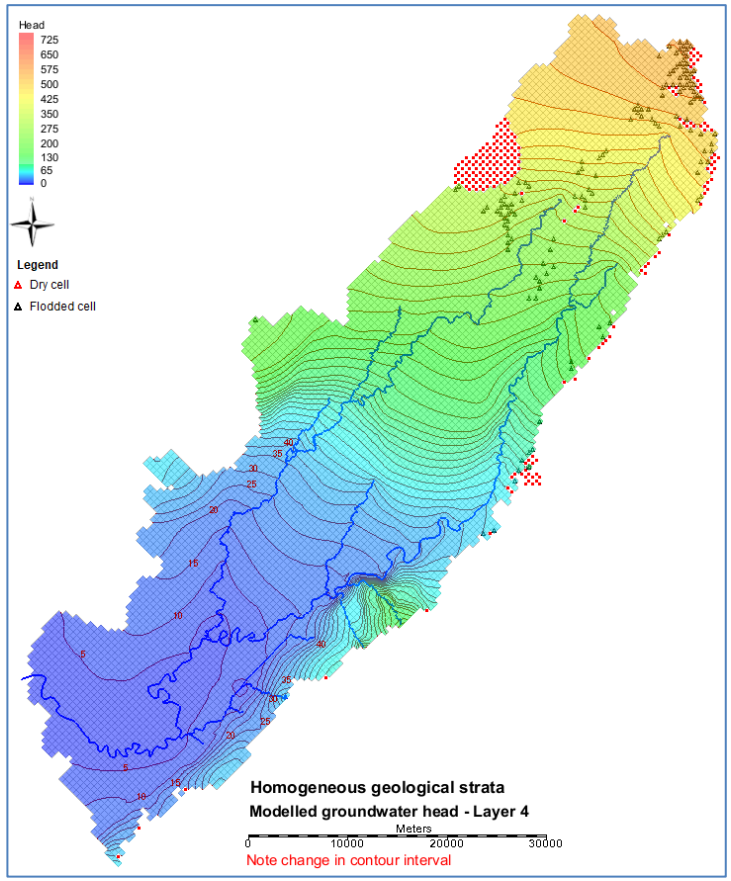

Figure E-5. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 4 assuming homogeneity of geological strata.

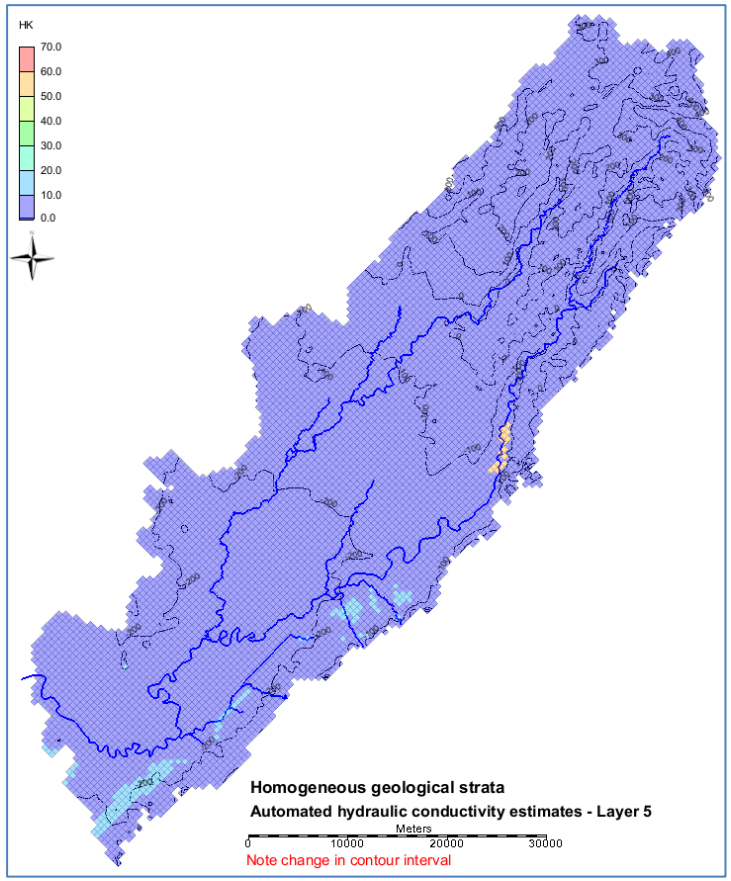

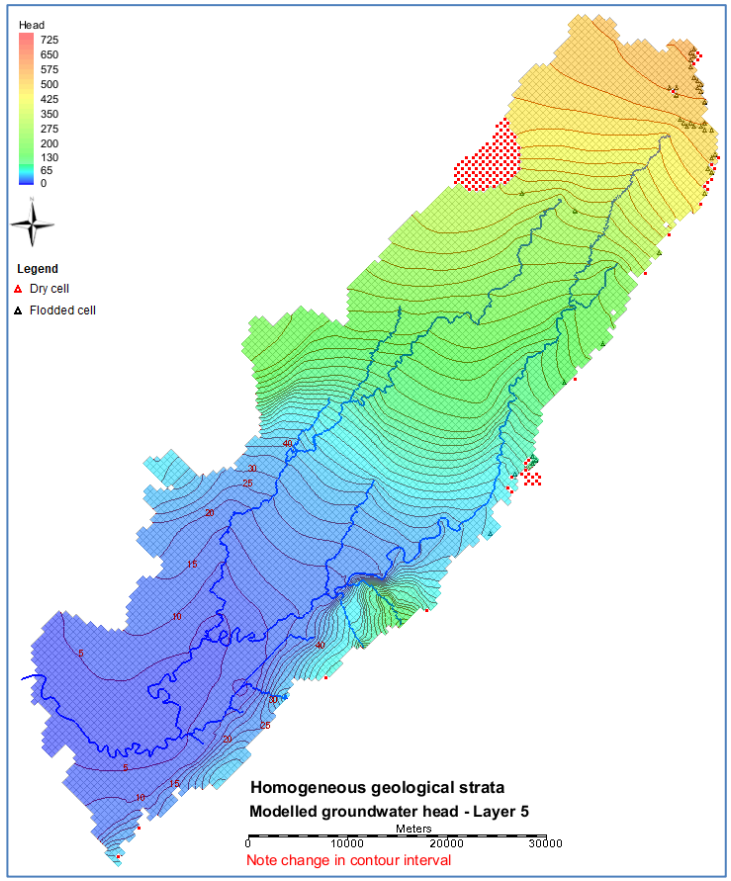

Figure E-6. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 5 assuming homogeneity of geological strata.

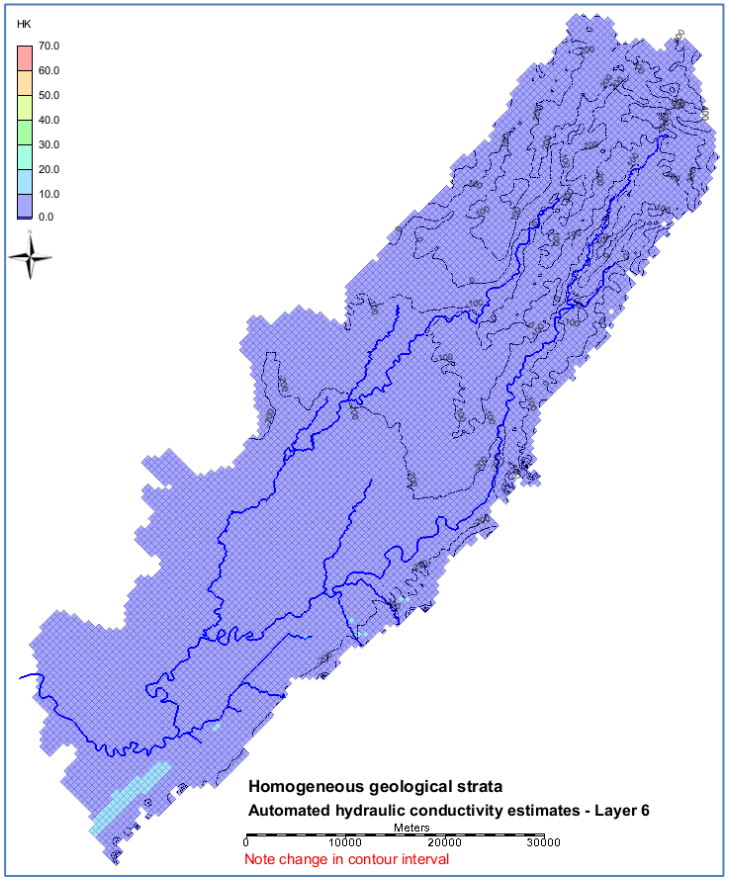

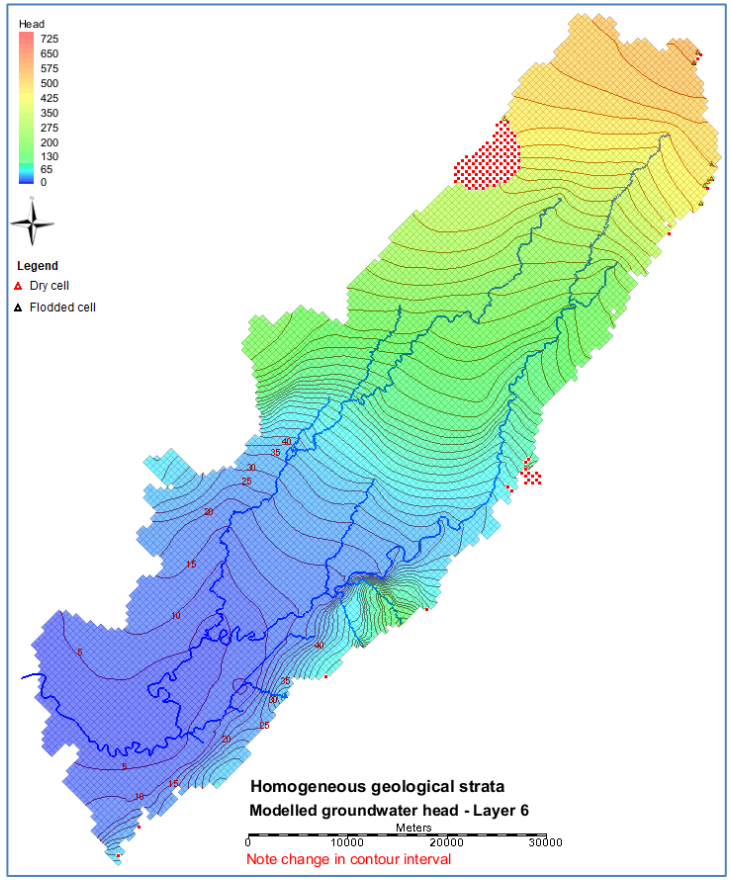

Figure E-7. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 6 assuming homogeneity of geological strata.

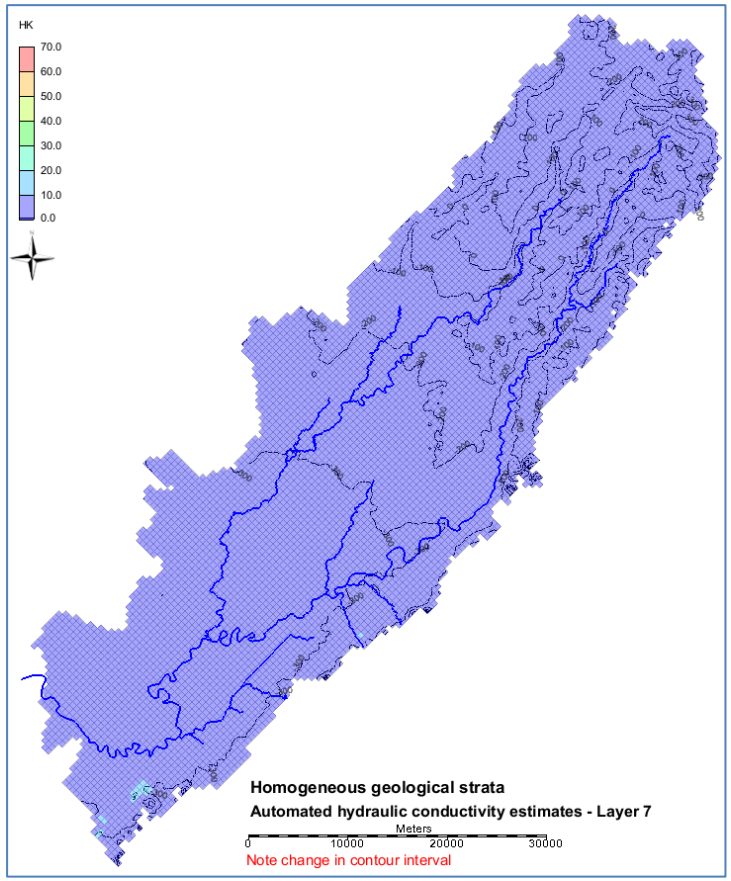

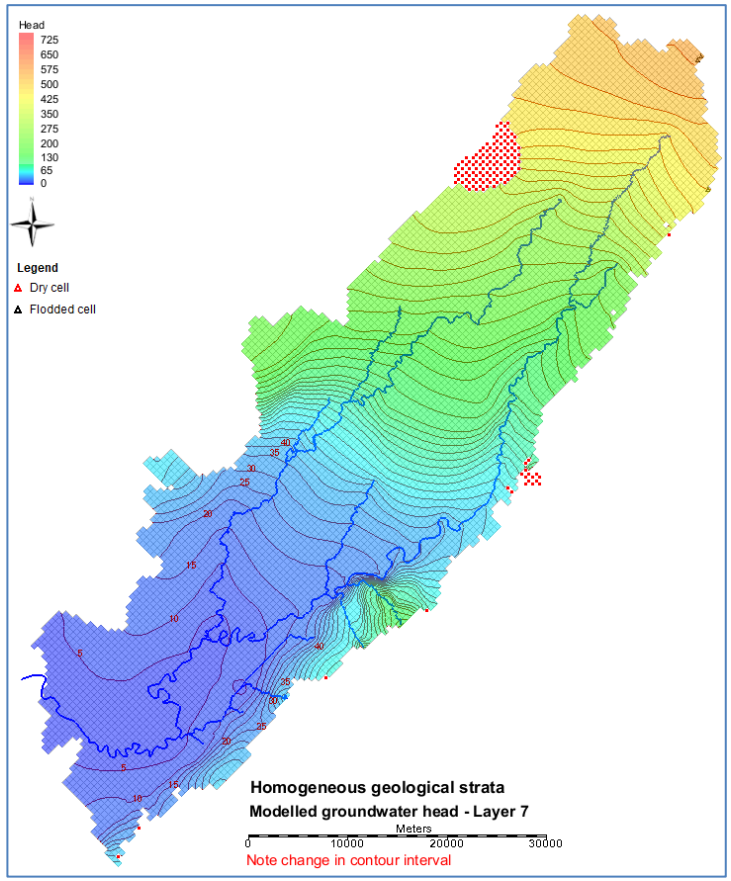

Figure E-8. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 7 assuming homogeneity of geological strata.

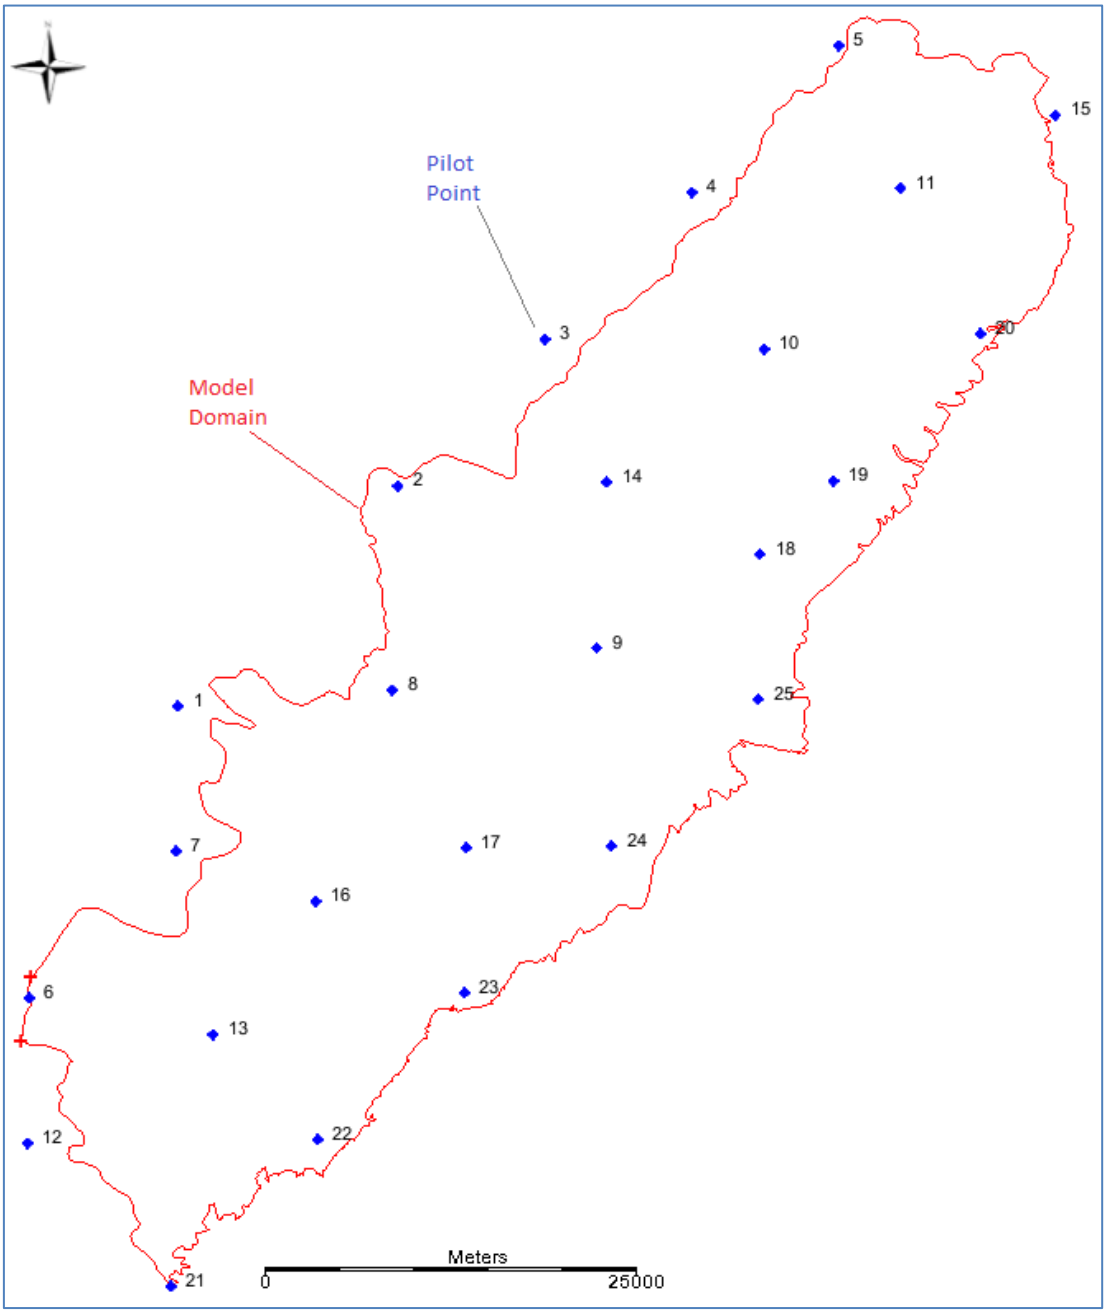

Figure E-9. Map showing the distribution of pilot points for use in automated estimation of hydraulic conductivity assuming heterogeneous geological strata. Labels are point ids.

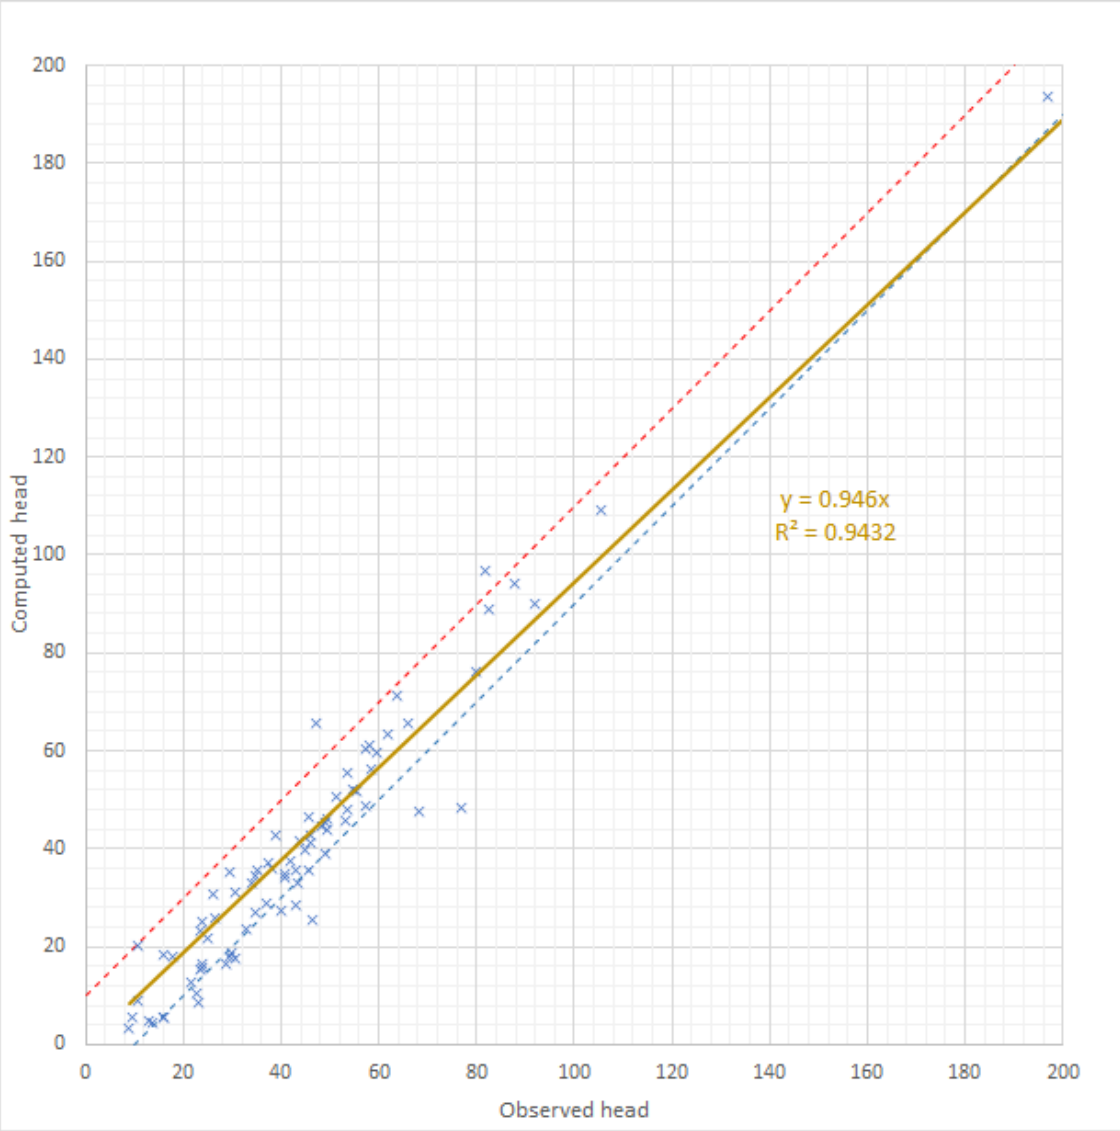

Figure E-10. Scatter plot of measured heads against model calculated heads from automated estimation of hydraulic conductivity assuming heterogeneous geological strata and using river/stream bed conductance values from Figure 8-9. The brown solid line represents the data linear trend, the red dashed line represents 10 m model overestimation, and the blue dashed line represents 10 m model underestimation. The trend line equation and linear regression goodness-of-fit (R^2) are shown on the graph.

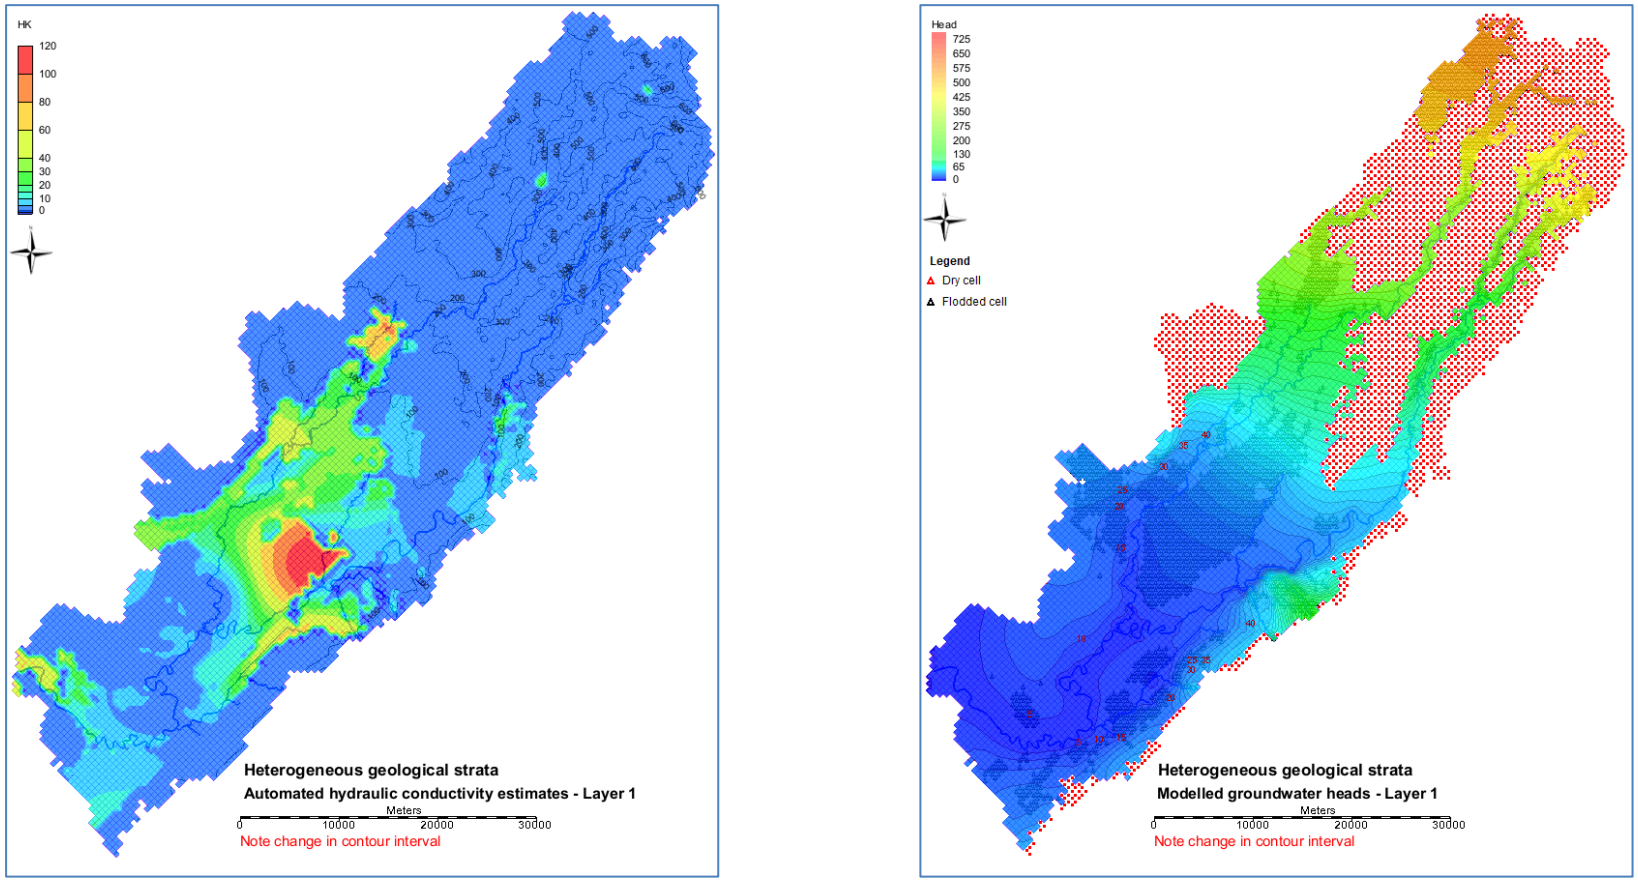

Figure E-11. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 1 assuming heterogeneity of geological strata.

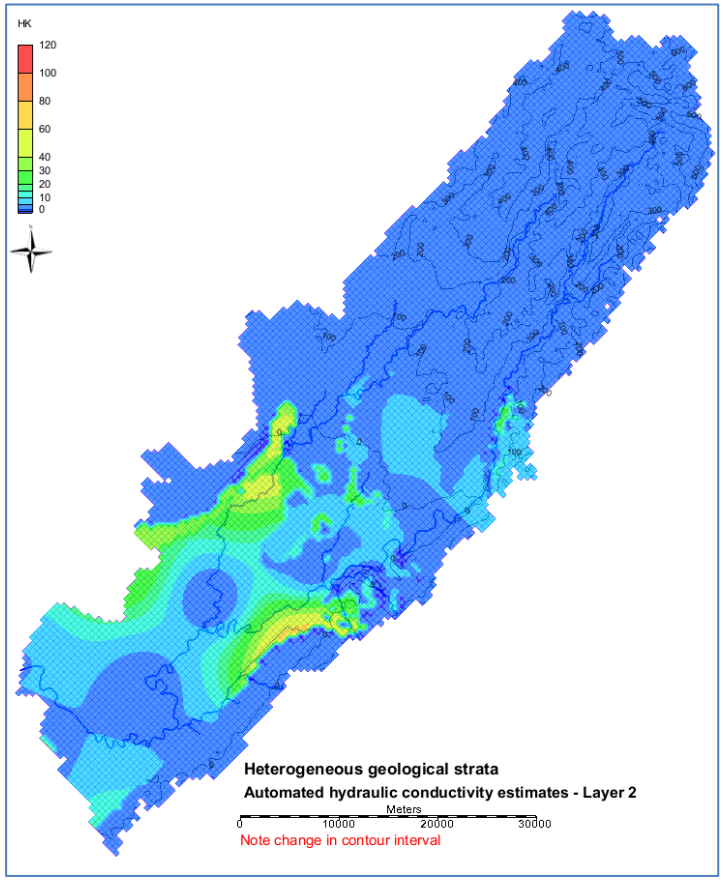

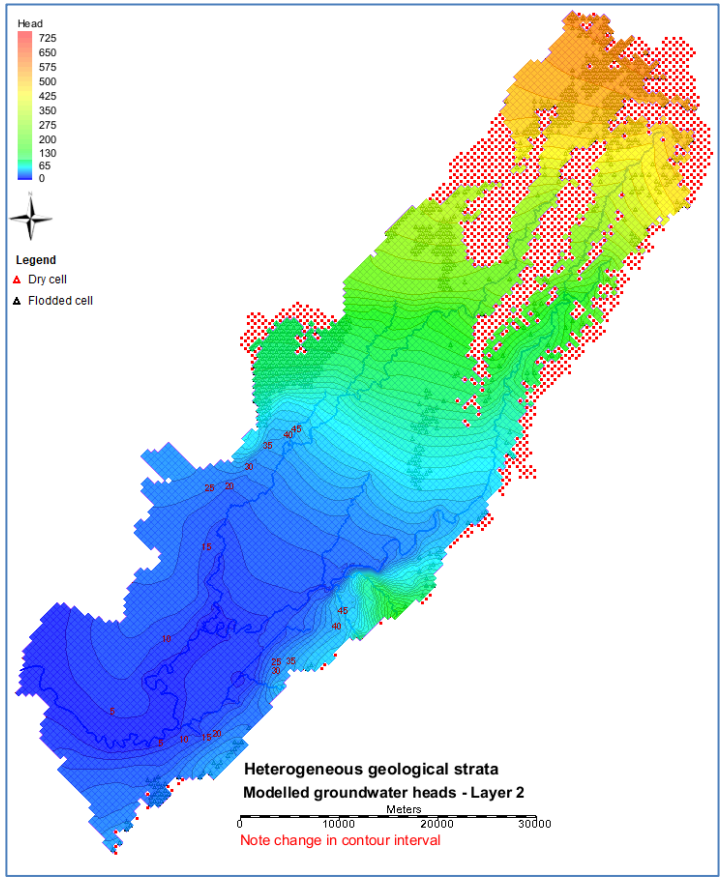

Figure E-12. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 2 assuming heterogeneity of geological strata.

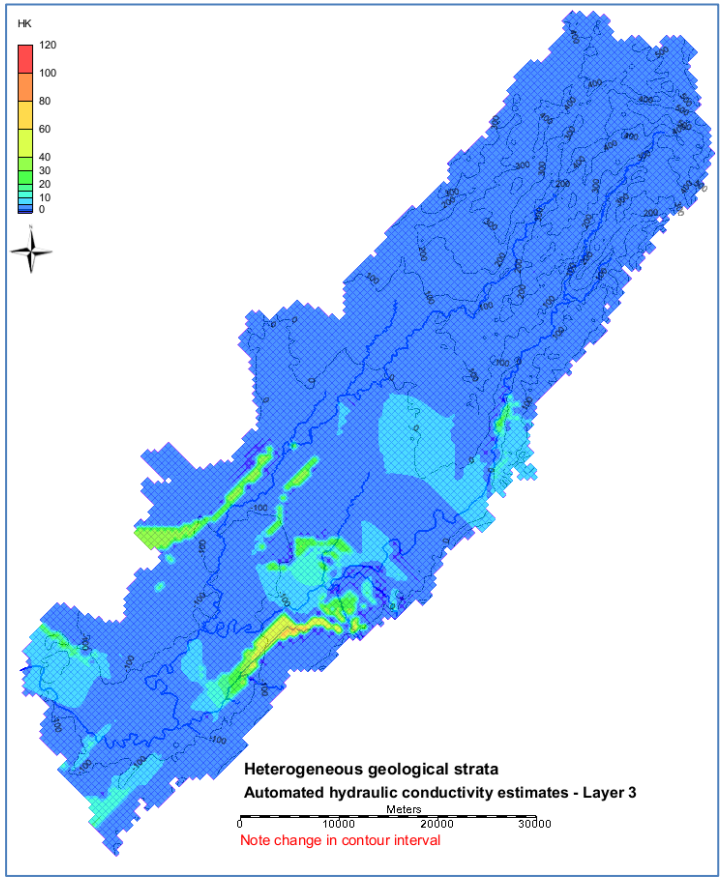

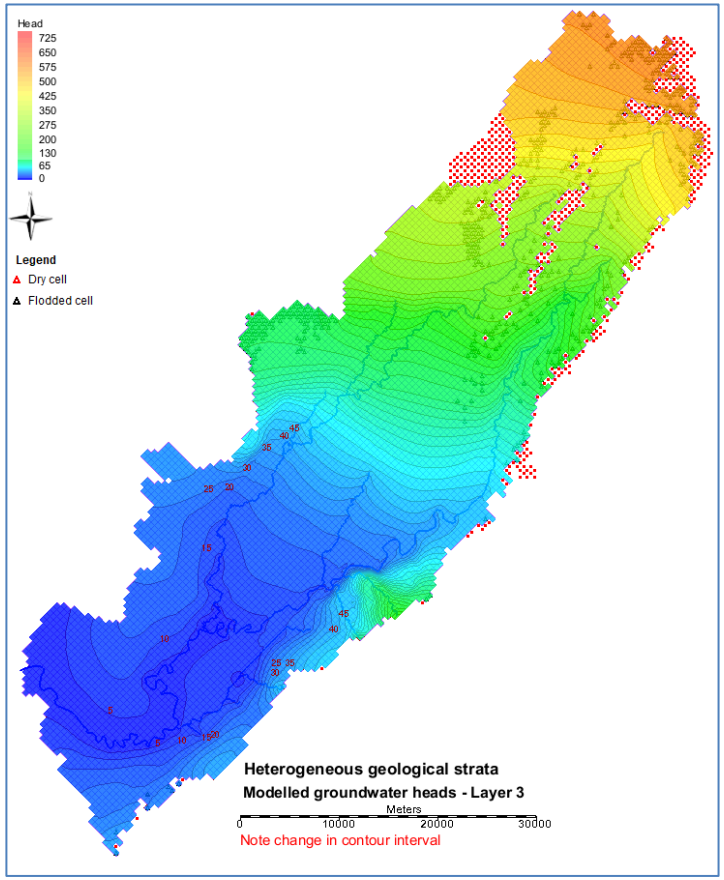

Figure E-13. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 3 assuming heterogeneity of geological strata.

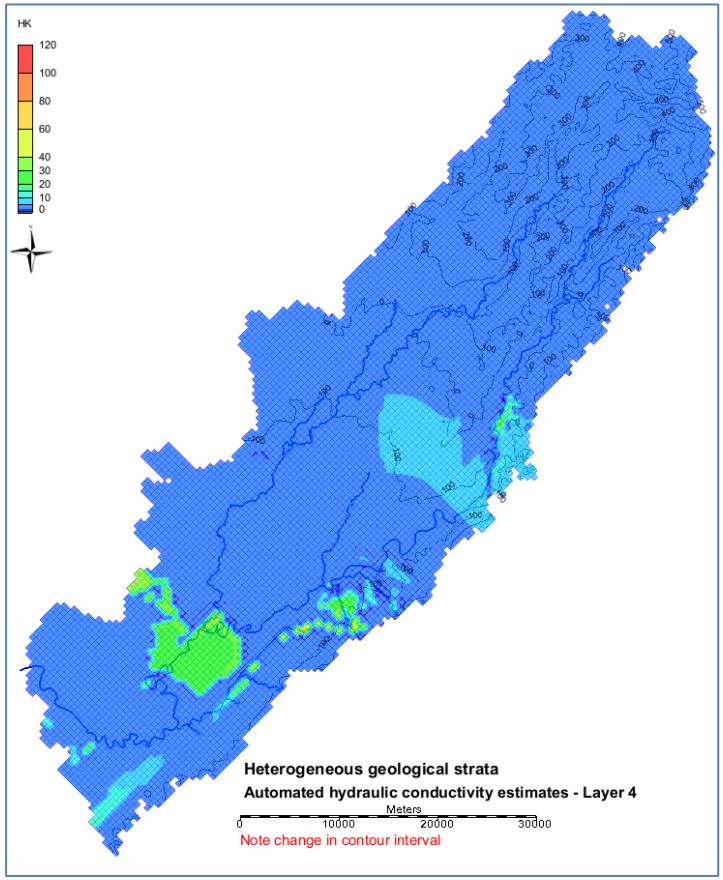

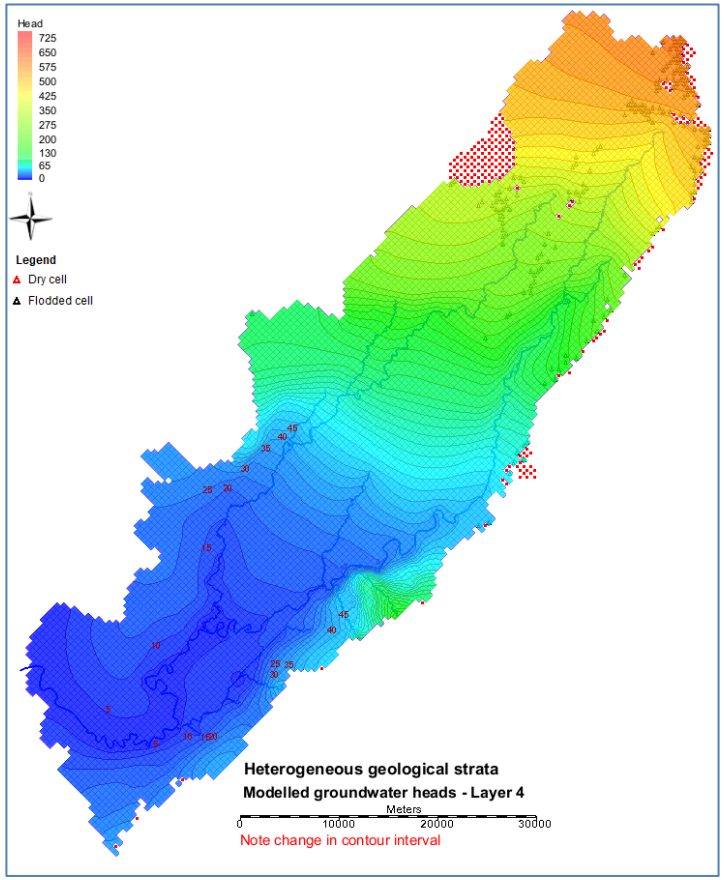

Figure E-14. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 4 assuming heterogeneity of geological strata.

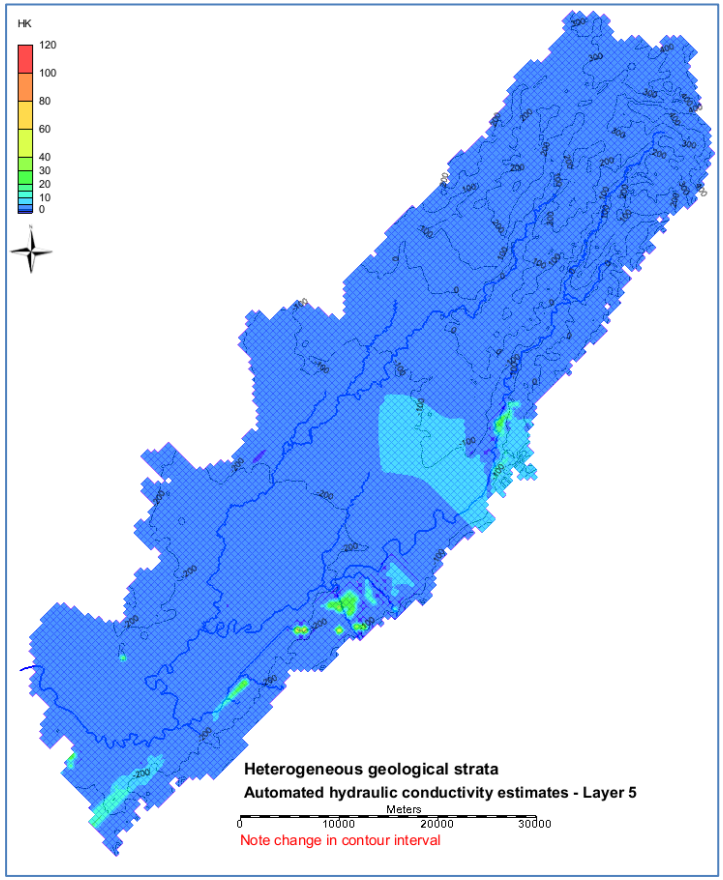

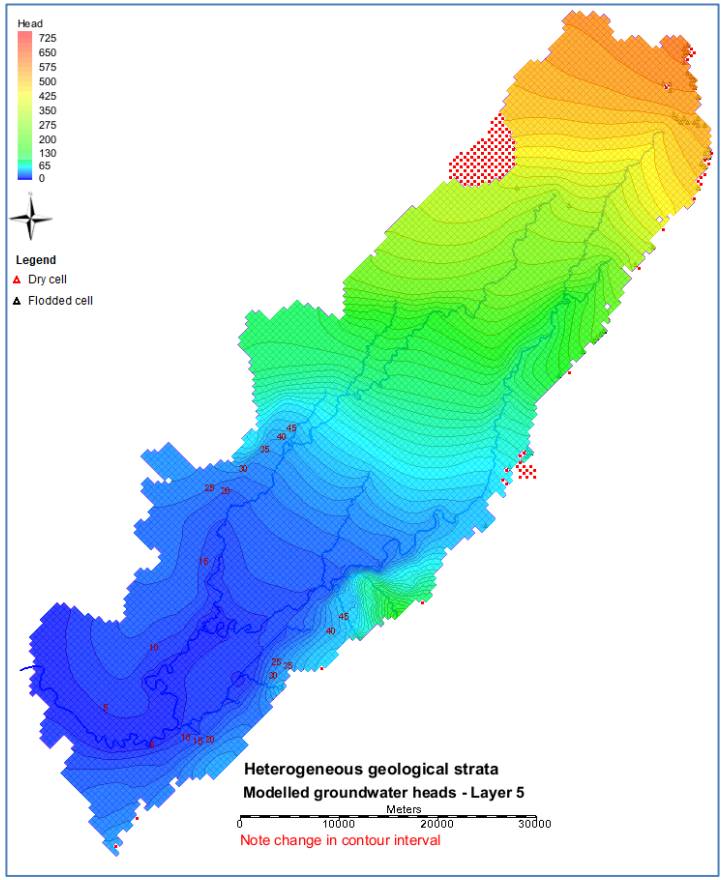

Figure E-15. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 5 assuming heterogeneity of geological strata.

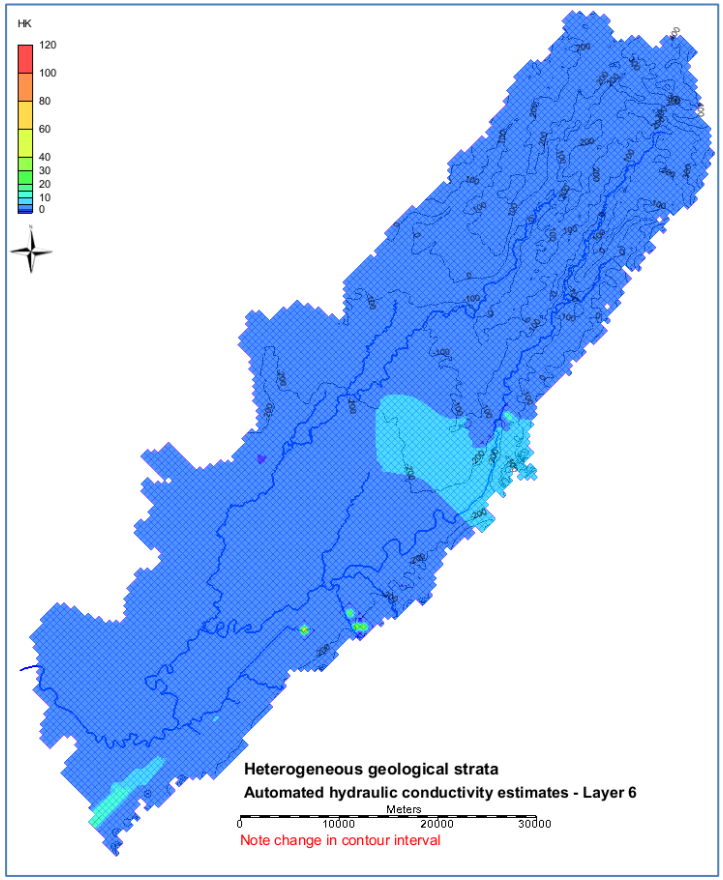

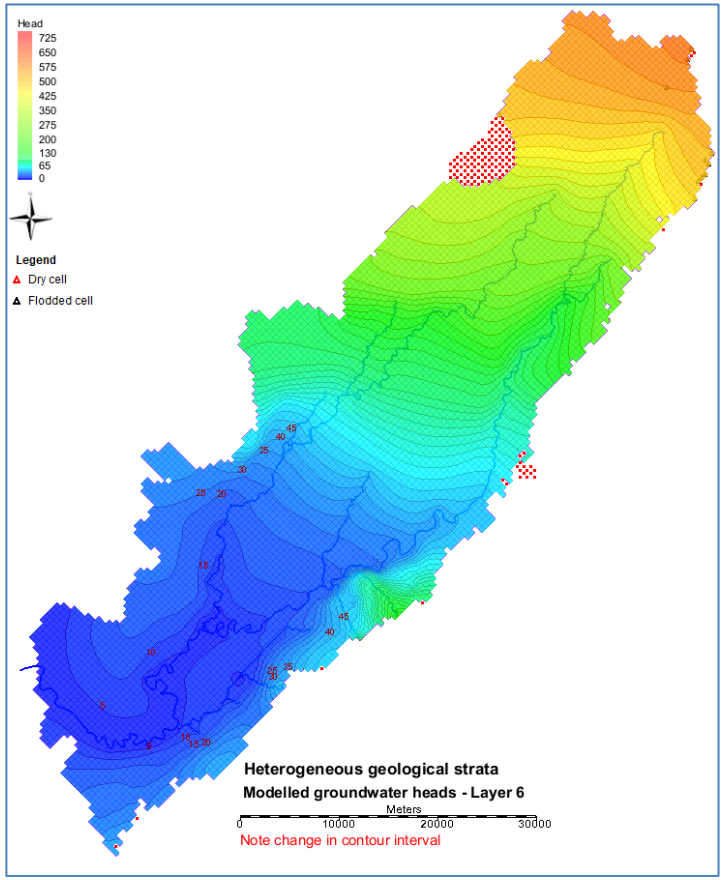

Figure E-16. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 6 assuming heterogeneity of geological strata.

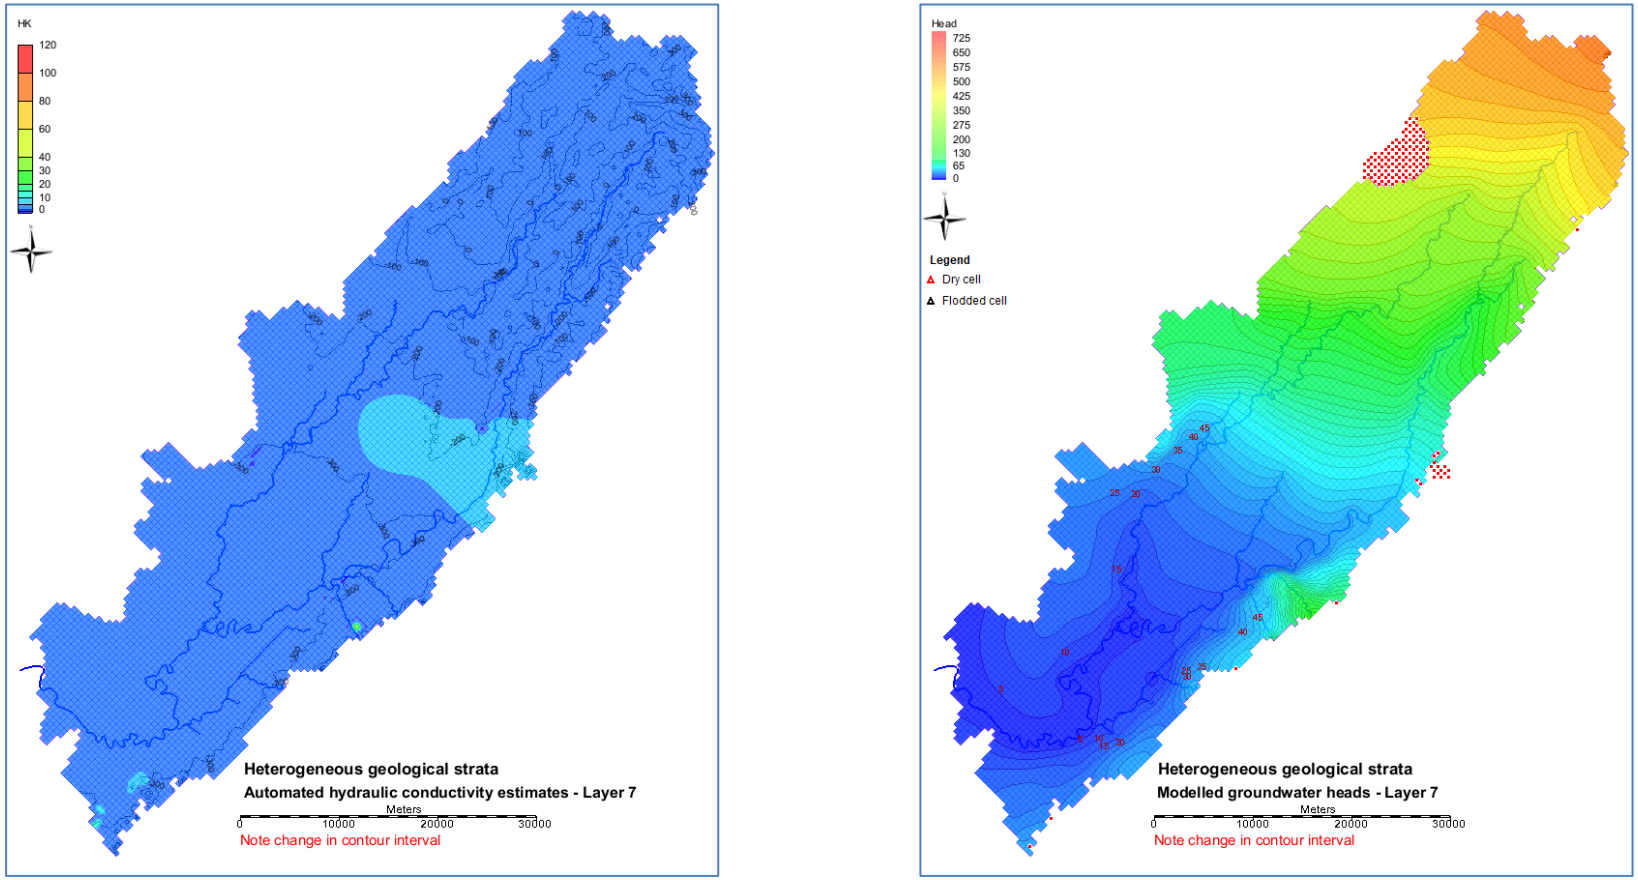

Figure E-17. Contour map of top elevation, automated estimates of horizontal hydraulic conductivity and computed groundwater head for model layer 7 assuming heterogeneity of geological strata.
