**Growth of dairy heifers on alternative forages and the effects of heifer live weight on reproductive parameters at first breeding.**

A thesis presented in partial fulfilment of the requirements for the degree of

Masters of AgriScience

in

Agriculture

at Massey University, Palmerston North,

New Zealand

Ross Patrick de Clifford

2015

# **ABSTRACT**

## **Abstract**

Dairy heifers in industry at present are frequently falling short of the recommended liveweight targets. Rearing of dairy heifers is expensive and involves a two-year non-productive period after which, if she becomes pregnant, income can be received from milk production. Milk yield in first and second lactation is affected by a heifer's live weight prior to calving and therefore meeting liveweight targets is critical for subsequent milk production. Those heifers that fail to become pregnant are of considerably lower value than those that become pregnant. To maximise the chance for heifers to become pregnant, heifers need to have completed a number of oestrus cycles prior to the planned start of mating. Mating of heifers during the third oestrus cycle compared with the first oestrus cycle after reaching puberty, provides an increased probability of the heifer becoming pregnant.

This thesis contains two experiments. The aim of the first experiment was to measure the effects on average daily gain, wither height, girth and crown-to-rump length, of feeding 6-month-old dairy heifers on alternative feeds, over the summer period when pasture quality and availability is limiting. Sixty 6-month-old Friesian-Jersey crossbred heifers were assigned to 1 of 3 treatments (pasture (P), conserved forages (C) or Lucerne (L), with all treatments receiving supplementary meal). Heifers were weighed at 0, 3 and 6 weeks of treatment period, and wither height, girth and crown-to-rump length were measured at the start and end of the experiment. L heifers had a greater ( $P < 0.05$ ) average daily gain ( $1.22 \pm 0.03$  kg/day) than P heifers ( $0.57 \pm 0.03$  kg/day), and C heifers were intermediate ( $0.78 \pm 0.03$  kg/day).

The aim of the second experiment was to determine the effect that live weight, percentage of individual liveweight target achieved and achieving individual liveweight target at 6, 9, 12 and 15 months of age had on 5 reproductive parameters: reaching puberty by 12 & 15 months of age; becoming pregnant during a 7 week mating period; becoming pregnant in the first 3 weeks of mating; and becoming pregnant in the first 6 weeks of mating. Heifer live weights were recorded approximately every month. Scanning of the heifers' ovaries at 12 and 15 months of age was completed to determine whether each heifer had reached puberty by the respective age. Natural mating was completed over a seven-week period, and age of the fetus was estimated at pregnancy scanning was to determine in which cycle the heifer became pregnant. There was no

effect on the pregnancy parameters measured as a result of live weight, reaching live weight target and the percentage of liveweight target achieved. Heifers that were heavier at 6, 9 and 12 months of age had an increased likelihood of reaching puberty by 12 months of age. Increased average daily gain was achieved from heifers grazing Lucerne, with supplementary meal also fed, although these increased average daily gains had limited benefit on reproductive performance of the heifers at first breeding.

# **ACKNOWLEDGEMENTS**

## **Acknowledgements**

I am extremely grateful to my supervisors, Dr Rebecca Hickson and Dr Penny Back for time and work that they have spent in assisting me in completing this thesis. I have learnt a lot throughout the last two years from both of my supervisors and I am sure I will take these lessons learnt with me into the future. I would also like to thank IVABS technician Natalia Martin for assisting in the completion of all the field work required to complete the experiments within this thesis. Additionally, I would like to thank technician Geoff Purchas for assisting in the completion of field work. I would like to thank the technical assistance provided by Mr Neil Smith (Massey University Riverside Farm Manager), Mrs Barbara Adlington and Ms Anne Tunnicliffe for their technical assistance in completion of laboratory work required for faecal egg counts and faecal eczema spore count completion, and Dr. Will Tulley for his technical assistance.

The completion of the research required in this thesis would not have been possible without the funding provided by the Massey University Research Fund, the McGeorge Research Grant and Massey Agricultural Experimental Station, and I am grateful for the provision of this financial support. The personal financial support provided through scholarships by the Landcorp Farming “First Step” Bursary, the Helen E Akers Postgraduate Scholarship, the Peter During Scholarship and the D J McGowan Scholarship were all greatly appreciated.

I would like to thank my friends and fellow post-graduate students: Cindy Little, Kelly Collier, Jordan Berry, Nicola Law, Sulav Shrestha, Heidi Anna Jack, Isabel Tait, and Rhiannon Handcock, to name a few, for providing me with entertainment throughout the two years it has taken to complete this thesis. If it was not for the support provided by them I would not have been able to get through the long nights and long weeks spent in the post-grad study room. Also, I would like to thank my flatmates for providing me with a house that feels just like home and plenty of moments that I will remember for a many years to come.

Finally, I would like to thank my family for providing the support needed to enable me to complete this thesis. There have been many times when a brief phone call or a home cooked meal has allowed me to relax and to unclutter my thinking allowing me to get back on track.
